However, Anderson and Mehl's results on the primary recrystallization of pure aluminum show that at 625°K, for example,  $Q_G$  and  $(\Delta S_A)_G$  are practically as large for a strain of 0.10 as for a strain of 0.02. These results cannot be reconciled with the inclusion hypothesis, unless it is supposed that recovery reduces the energy of cold working to a value almost independent of strain before boundary migration begins.

### Summary

- 1—The relation between grain boundary migration rates and diffusion coefficients is derived on the basis of the absolute reaction rate theory.
- 2—It is shown that in lattice self-diffusion the free energy of activation greatly exceeds that in grain boundary migration.
- 3—A corollary of 2 is that in grain boundary migration the atomic mobility is many orders of magnitude larger than in lattice self-diffusion.
- 4—In silver the free energy of activation for grain boundary self-diffusion equals that for grain boundary migration, within the experimental uncertainty.
- 5—The apparent entropy of activation for boundary migration is much larger than for self-diffusion processes.
- 6—An explanation for the unexpectedly large entropy of activation in boundary migration processes is given based on the concept that inclusions retarding boundary migration become less effective at elevated temperature due to their solution and coalescence.

# Effects of Manganese and Its Oxide On Desulphurization by Blast-Furnace Type Slags

by Nicholas J. Grant, Ulf Kalling, and John Chipman

THE operation of a blast furnace is dependent to an important extent upon the sulphur content of materials charged and the desired limit of sulphur in the product. It has long been known that the blast furnace is the most efficient tool for desulphurization in common use and that this efficiency is associated with the strongly reducing conditions of the hearth and is enhanced by increased basicity and fluidity of the slag. The chemical reactions of desulphurization may be studied from the viewpoint of the ratio of the process or of the final equilibrium conditions. Both kinds of studies contribute to an understanding of the process and both are included here.

A simple measure of the desulphurization power of a slag is given by the ratio:

$$\frac{\text{Pct sulphur in slag}}{\text{Pct sulphur in metal}} = \frac{(\text{Pct S})}{[\text{Pct S}]}$$

This ratio was used by Holbrook and Joseph<sup>1, 2</sup> to measure relative desulphurizing powers under controlled laboratory conditions. It was also used by Hatch and Chipman<sup>3</sup> as a measure of the equilibrium distribution. For the latter purpose it would be preferable to employ thermodynamic activities rather than percentages, but until very recently this has been impossible for lack of data. Now, thanks to the work of Morris and Williams<sup>4</sup> and Morris and Buehl,<sup>5</sup> the effects of carbon and silicon upon the activity of sulphur in the metal are known. The confirmation of this work and its extension to include the effects of other elements by Sherman and Chipman<sup>6</sup> and by Rosenqvist and Cox<sup>7</sup> make it possible to calculate the activity of sulphur in pig iron of any composition. Hence it is now possible to use data on the equilibrium distribution of sulphur to find its activity in the liquid slag and to approach an ultimate solution of the thermodynamic aspects of the problem.

The rate of transfer of sulphur from metal to slag is the problem of major industrial importance and indeed the principal need for equilibrium data has been as a necessary adjunct to the kinetic studies. The rate of approach to equilibrium under laboratory conditions seems slow compared to the requirements of industrial practice, and it is clear that further laboratory studies of rates are needed.

In the research reported below, the items which were investigated were the following: 1—The role of mechanical stirring on the approach to equilibrium. 2—The role of MgO in desulphurization as compared to CaO. 3—The role of MnO in desulphurization. 4—The limiting reactions which constitute the slow steps in desulphurization.

## Experimental Procedure

The experimental set-up and procedure previously described by Hatch and Chipman<sup>3</sup> were essentially followed with several small modifications. The graphite crucible containing the slag and metal charge was altered to provide considerably more

Fig. 1—Modified graphite stirrer and crucible.

active stirring and mixing of the slag and metal in the carbon monoxide atmosphere. For this purpose the crucible was machined to provide two deep cylindrical wells which were interconnected at top and bottom as shown in Fig. 1. A graphite screw with a flat thread and of shallow pitch (4 threads per in.) spinning at 600 to 800 rpm was used to lift the slag and metal over the partition between the two wells and throw them over into the second well, where the metal settled through the slag into the reservoir at the bottom. It was possible to see actual particles of slag and metal being thrown over the partition. In this respect, the stirring was more vigorous than used in the work of Hatch and Chipman.

A charge of 400 g of wash metal was first melted, and 20 g of FeS was then added to yield a bath containing 1.65 pct S. Immediately 400 g of slag (as pure mixed oxides) was added and fused. The slag was generally fused in 1 hr  $\pm$  10 min. Within 30 to 45 min after melting, the temperature was adjusted to 1525°C, and the first slag and metal samples were taken. The slag was picked up on the end of a cold Armco iron rod, whereas the metal was sucked into a silica tube.

The wash metal composition was (in percent): 4.29 C; 0.022 S; 0.021 P; 0.38 Si. The slags used were of four fixed starting compositions covering a wide range of acid-base ratios shown in Table I. Deliberate variations in MgO were made in these slags to check the role of MgO in blast-furnace desulphurization. Changes due to additions and reactions were followed by analysis of samples.

Additions of Mn and MnO were made to most of the heats to note the role of Mn and MnO on desulphurization. Three heats (62 through 64) were made in an open pot induction crucible (graphite) using a

Fig. 3 (right)—Desulphurization of iron by slag IV at 1525°C as a function of time.

slag virtually free of  $\text{SiO}_2$  to study the role of Si and  $\text{SiO}_2$  on desulphurization. A carbon monoxide atmosphere at an excess pressure of  $\frac{1}{2}$  to 1 in. of water was kept constantly over the melt.

Optical temperatures were read frequently throughout the course of a heat by sighting down the graphite tube (stirring shaft) to which the immersed stirrer head was attached. Periodic checks with a platinum thermocouple established the temperature errors to be  $\pm 5^\circ\text{C}$ , and deviation from  $1525^\circ$  during a run seldom exceeded this figure.

The stirrer was started as soon as the slag was molten, and this point was taken as zero time.

The compositions of the slag and metal samples are shown in Table II. Table III shows the nature and the time of the additions made to each slag.

**The Effect of Slag Basicity:** The sulphur content of the metal is plotted against the heat time at  $1525^\circ\text{C}$  for each grade of slag in Figs. 2 to 5 with Fig. 2 being slag III, the most acid and Fig. 5 being slag II, the most basic. Zero time is the time when the slag is first judged to be molten. For heats 66 through 80 the time from "start to add cold slag" to "slag molten" ranged from 35 to 65 min except heat 73 which took 120 min.

In each of Figs. 2 to 5 there is a "no addition" heat and these are compared in Fig. 6 from which it is very apparent that the basicity of the slag is an extremely important factor in controlling the speed of the desulphurization reactions and the final sulphur content of the metal. An approximate relationship between basicity, as measured by "Excess  $\text{CaO}$ " and the time required to reach equilibrium is shown in Table IV.

**Effect of Stirring:** While there is no direct measure of the difference in stirring effectiveness in the present heats compared to those of Hatch and Chipman,<sup>9</sup> it is believed from observations that the present stirring method was much more vigorous. Nevertheless, the time to reach sulphur equilibrium

for similar heats of the acid type in both groups of experiments was of the same order, indicating that for these rather fluid slags the added surface content was not too important a factor in the speed of the reactions. The initial desulphurization rate for all slags must be unusually high since the metal contains 1.65 pct S at the start and drops to the levels shown as the first values in Figs. 2 to 5 in 1 to 2 hr.

**Role of MnO in Blast-Furnace Slags:** Figs. 2 to 5 show the effects of Mn and MnO when added to the initial charge or during the course of a heat. The arrow in each figure shows the time of the addition. When added during the heat, a very interesting and important effect is noted in that immediately after the addition of MnO there is for each slag and in every instance a reversion of sulphur into the metal. These 4 heats are shown in Fig. 7. The full extent of the reversion is not accurately determined because a sufficient number of samples were not taken during this period.

The cause of the sulphur reversion can be ascribed but to one effect and that is the temporary reoxidation of the slag through the reduction of MnO. This is especially interesting when it is considered that MnO is a basic oxide; the expected beneficial effect of the basic addition has been overshadowed by the adverse effect of oxidation. The same or greater effect could have been achieved by the addition of the more easily reducible oxide FeO to the slag which is known to affect adversely the desulphurizing power of slags of this type.<sup>8</sup> It will be noted that recovery of the system from the oxygen addition is more rapid the more basic the slag.

Table II shows that most of the MnO is reduced to Mn in the metal. The maximum MnO remaining in any of the heats (nonequilibrium) is only 1.3 pct in the most acid slag while Mn in the metal runs as high as 5 pct.

Of great current interest is the effect of basicity on the MnO reduction from the slag. Manganese recovery is defined as the ratio of Mn in the metal to total manganese. This ratio is plotted in Fig. 8 against Excess Base. A very similar curve was obtained using Excess  $\text{CaO}$  with about the same degree of scatter of points. Fig. 8 shows that with the most basic slags a recovery of about 96 pct of the manganese may be achieved, under near-equilibrium conditions. The most acid slag with essentially zero Excess Base shows 82 pct Mn recovery. The curve

shown in Fig. 8 does not represent equilibrium values, since MnO was still in the process of being reduced as shown in Fig. 9.

The effect of manganese on both desulphurization rate and equilibrium is very small and is confined to the two less basic slags. Disregarding the heats in which MnO was added during the experiment and considering only those in which Mn and MnO were included in the charge, the curves of the most acid slags shown in Figs. 2 and 3 indicate that the time required to reach a given sulphur level is slightly shortened by the addition. At the same time the final distribution is slightly improved; this is evident in the most acid slag where the effect is greatest.

If the "manganese recovery ratio" is plotted against time, the curves shown in Fig. 9 for the 4 types of slags are obtained. These curves show the approach to manganese equilibrium with time as a function of basicity. As would be expected, the most basic slag (II) approaches equilibrium most rapidly, but even at 96 pct recovery has not reached equilibrium. The break in the curves for slags II and IV is due to a 2 pct MnO addition to the slag, and shows that the MnO is rapidly reduced. Heat 77 (slag III) did not have Mn and MnO charged initially as did the others and so does not have the same "zero."

The curves of Fig. 9 are almost a mirror image of the curves of Figs. 6 and 7 for desulphurization, the

transfer of manganese and sulphur being in opposite directions. This suggests that MnO in the slag or the manganese recovery ratio might be a useful indicator for estimating the basicity of the slag but especially its degree of oxidation.

FeO is too easily reduced, leaving quantities of less than 0.1 pct in the slag. Such a small amount is too difficult to analyze correctly. MnO, on the other hand, is less readily reduced than FeO, is more easily analyzed, and approaches equilibrium in about the same time as sulphur.

Values of "manganese recovery ratio" for the blast furnace strongly suggest that in the blast furnace the slags are not as thoroughly reduced as the slags reported in this research (for a given basicity). This would correspond to a higher degree of oxidation of the slag, causing the lower desulphurization ratios noted in the blast furnace compared to comparable basic slags reported in this work.

**Effect of MgO:** One of the aims of this research was to establish the effect of MgO on the desulphurizing power of the slag. For this purpose the starting slags were made up with 2 or 10 pct MgO. Since the principal desulphurizing oxide is known to be CaO, the subsidiary effect of MgO can be found by comparing slags with or without this component. The comparison is shown in Fig. 10 where the ratio (pct S)/[pct S] in the final samples is plotted against

Fig. 4 (left)—Desulphurization of iron by slag I at 1525°C as a function of time.

Fig. 5 (right)—Desulphurization of iron by slag II at 1525°C as a function of time. Inset based on expanded sulphur scale.

Fig. 6 (left)—Comparison of slags I to IV showing pronounced effect of slag basicity on rate of sulphur removal and final sulphur. All "no addition" heats.

Fig. 7 (right)—Comparison of slags I to IV wherein Mn and MnO are added during the heat.

Excess Base. The latter is defined here as the excess number of mols of  $\text{CaO} + \text{MgO}$ , per mol of slag, over and above that required to form compounds of the type  $\text{CaSiO}_3$  and  $\text{CaAl}_2\text{O}_4$ . The straight line is taken from Sherman and Grant's<sup>9</sup> treatment of Hatch and Chipman's<sup>8</sup> data, adjusted slightly for the difference in temperature. The points for 2 pct MgO fall slightly below this line, those for 10 pct considerably below. The one point for a simple lime-alumina slag is on the line.

Fig. 11 is a plot of the same points as in Fig. 10 except that basicity is expressed as "Excess CaO" as defined by Sherman and Grant.<sup>9</sup> The solid line is the same line as the Zero MgO line of Fig. 10; and it is to be noted that the points fall uniformly about this line within the limits of an error of 0.001 pct S in the metal which is represented by the dashed lines. For comparison, the curve at 1500°C based on the work of Hatch and Chipman is also included (dotted line).

There is no preferential grouping of points in Fig. 11 on the basis of MgO content. Thus Figs. 10 and 11 confirm that whereas MgO is equal to CaO on a molar basis in the neutralization of  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$ , only CaO is truly effective in the desulphurization of iron.<sup>9</sup> It should be added that the term Excess CaO merely serves as an approximate measure of CaO activity in the range of compositions for which it is used.

The simple sulphur ratio in weight percent has

Fig. 8—Manganese recovery as a function of Excess Base at 1525°C.

been used throughout this work. This was desirable first because a direct comparison was permitted with the results published by Hatch and Chipman,<sup>8</sup> and second because the data on sulphur activity in the metal in the presence of other elements is not yet complete.

**Factors Affecting the Rate of Desulphurization:** Recently, Derge, Philbrook and Goldman<sup>10</sup> suggested that of three probable reactions applicable to desulphurization occurring in the blast furnace, the limiting reactions were the heterogeneous reactions involving the transfer of Fe and S to the slag and the reduction of FeO from the slag by C.

The present research indicates that this is only true to a limited extent, but that other factors are operative which previously had not been investigated thoroughly enough. It is noted that:

1—Fig. 6 shows the profound effect of basicity on the desulphurization rate which suggests that the C plus FeO reaction is in turn controlled by other reactions.

2—Fig. 7 shows the rapid response of metal sulphur to oxygen and its equally rapid recovery from the effect of oxygen (from MnO) in all slags regardless of basicity.

Table III. Nature of Additions Made to Each Heat

| Heat | Slag                               | Additions to Slag or Metal*                  |

Fig. 9—Manganese recovery as a function of time for slags I to IV at 1525°C.

Fig. 10—Desulphurization ratio vs. Excess Base at 1525°C comparing 2 and 10 pct MgO slags relative to the zero MgO line for slags of 1.65 pct S.

Fig. 11—Desulphurization ratio vs. Excess CaO at 1525°C showing 0.001 pct S limits. Dotted curve for 1500°C.

3—A large increase in stirring efficiency did not materially increase desulphurization rates in the slower more easily observable acid heats.

These observations coupled with an examination of the analytical values in Table II suggested  $\text{SiO}_2$  reduction might in fact be the controlling reaction.

Accordingly, a heat was made using a slag composed of 50 pct by weight of both  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$ , a slag virtually free of  $\text{SiO}_2$  or other reducible oxides. This heat, No. 64, shows that for a slag with Excess  $\text{CaO}$  of 0.442 the iron was completely desulphurized in less than 40 min from the time of the first, unfused, cold slag addition. The heat was made in a graphite crucible open to the air and therefore was not made under as ideal reducing conditions as the other heats. A very violent gas evolution accompanied the desulphurization reaction the moment the slag and metal were stirred.

From the above it would appear that it is not the C and  $\text{FeO}$  reaction which makes the desulphurization process slow. Instead it is the slow reduction of  $\text{SiO}_2$ . This reduction shifts the slag composition to greater basicity which tends to promote the desulphurization reactions but at the same time provides oxygen to the slag which prevents efficient desulphurization. The speed of the desulphurization reaction is directly related to the degree of oxidation of the slag. Easily reducible oxides such as  $\text{FeO}$  offer little impediment to desulphurization, whereas oxides such as the more refractory  $\text{SiO}_2$  release oxygen slowly, maintaining an oxidized slag over a long period of time. This role of  $\text{SiO}_2$  reduction on the desulphurization reactions is to be the subject of a separate research program.

### Conclusions

1—Increased vigor of stirring the slag and metal has little effect on increasing the rate of desulphurization of iron for the more acid slags.

2— $\text{MnO}$  is readily reduced, reaching a reduction efficiency of 96 pct or more for the most basic slags.  $\text{MnO}$  remains in such small amounts in the slag that its influence is difficult to measure except in the most acid heats where it appears to increase the rate of desulphurization slightly.

3—Oxygen (from  $\text{MnO}$ ) causes an almost immediate sulphur reversion into the metal. The slag recovers more slowly. The response is more rapid the more basic the slag.

4—Manganese equilibrium is achieved more slowly than sulphur equilibrium but is of comparable time. Manganese recovery may serve as an indication of the degree of slag oxidation.

5—The two most important factors on the speed of desulphurization and on the final sulphur in the metal are the basicity of the slag and the degree of oxidation of the slag.

6—The basicity is best expressed by the value Excess  $\text{CaO}$ .

7— $\text{MgO}$  is a poor desulphurizer but can replace  $\text{CaO}$  in neutralizing the acid constituents.

8—The limiting reaction in controlling the rate of desulphurization is probably the reduction of  $\text{SiO}_2$  and not the heterogeneous reaction between C and  $\text{FeO}$ .

### Acknowledgments

The authors express their thanks to the American Iron and Steel Institute who sponsored this research program. They are grateful to Olaf Troili who participated in making all the experimental heats and especially to Charles W. Sherman for his many calculations and active participation throughout the program.

# Effect of Silica Reduction on the Desulphurizing Power Of Blast-Furnace Type Slags

by Nicholas J. Grant, Olaf Troili, and John Chipman

IN recent studies of the factors which affect the rate of desulphurization and its equilibrium, it became apparent that certain concurrent reactions were operative which had a significant effect on desulphurization. This is emphasized in the experiments of Hatch and Chipman<sup>1</sup> and of Grant, Kalling, and Chipman<sup>2</sup> by the slow approach to a final state of equilibrium which is in marked contrast to the initial rapid transfer of sulphur from metal to slag. Since the removal of sulphur is of such profound importance in iron and steelmaking, it appeared necessary to investigate the reactions responsible for this behavior.

It is now known that the presence of iron oxide in the slag interferes seriously with the principal reaction of blast-furnace desulphurization:

The interfering reaction is most simply expressed as:

and a small concentration of oxygen (or FeO) is sufficient to hold a considerable amount of sulphur in the metal.

It has been shown by Grant, Kalling, and Chipman<sup>2</sup> that the addition of MnO to blast-furnace slag slows the removal of sulphur from the metal. This effect overshadows the contribution of MnO to basicity and is ascribed to its oxidizing power.

It will be shown in this paper that SiO<sub>2</sub> also has sufficient oxidizing power to interfere with blast-furnace desulphurization. This is, of course, only one of its several effects. Primarily it is an acid and therefore reduces the concentration of excess lime. But when silicon is reduced to the metal the oxygen to which it was previously bonded becomes in part available for reaction 2. The proof of this statement is found in the following experiments.

## Experimental Procedure and Results

Utilizing the same procedure and apparatus described by Grant, Kalling, and Chipman<sup>2</sup> five additional heats were made using slags IV and II, the starting compositions of which were: slag IV—40 CaO, 10 MgO, 35 SiO<sub>2</sub>, 15 Al<sub>2</sub>O<sub>3</sub>; and slag II—50 CaO, 10 MgO, 25 SiO<sub>2</sub>, 15 Al<sub>2</sub>O<sub>3</sub>.

An important difference between these heats and those previously reported was that silicon to the extent of 1 to 4 pct was added to the present heats whereas the starting silicon content was formerly about 0.2 pct.

Table I shows the slag and metal analyses for heats 82 to 87, and Table II shows the silicon addi-

tions made to the charge. These additions are based on 400 g of metal and 400 g of slag. All heats had 1.65 pct S charged before the cold slag additions. The temperature was maintained at 1525°C.

**Rate of SiO<sub>2</sub> Reduction:** Fig. 1 shows the silicon content of the metal in contact with slag IV at 1525°C as a function of time. Heat 70 from the work of Grant, Kalling, and Chipman is included as the lowest starting silicon. It will be noted that even with 4 pct Si in the starting metal, there is an increase in silicon content with time. Heat 84 is apparently approaching silicon equilibrium very slowly. Heats 70 and 82 with very much lower starting silicon show a more rapid initial rise in silicon content but do not reach equilibrium during a long holding period.

Fig. 2 shows 3 different initial silicon contents for heats 73 (from Grant, Kalling, and Chipman) 86 and 87, in contact with slag II, the most basic slag. Heat 73 is increasing in silicon with time, whereas heat 87 with an initial silicon content of 3.7 pct shows a decrease with time. Heat 86 shows a very close approach to equilibrium. The rate of transfer of silicon from slag to metal is very slow in all of those heats, even those which are initially far from equilibrium.

Fig. 1—Increase in silicon content of metal with time for slag IV at 1525°C.

Fig. 3—Decrease in sulphur in metal with time for slag IV at 1525°C for heats of different initial silicon content.

**Effect of Silicon Content on Rate of Desulphurization and on Sulphur Equilibrium:** Figs. 3 and 4 show curves of sulphur in the metal vs. time at 1525°C for the same heats as in Figs. 1 and 2. Fig. 3 is for the more acid slag IV. It is very obvious that the addition of silicon to the charge affects profoundly the rate of sulphur removal. The effect on final sulphur is apparently smaller than the experimental uncertainties. The direct effect of silicon in the charge is to prevent or minimize the reduction of silicon from the slag thus depriving the silica of its oxidizing power.

Fig. 4 is for the very basic slag II, using an expanded ordinate of twice that of Fig. 3. For this slag also there is an effect on the desulphurization rate due to an initial high silicon content of the molten iron. Fig. 4 must be viewed with some caution, however. The very high basicity of slag II and the high desulphurization rate imply that some significant desulphurization must have occurred even before the slag was judged to be molten. Accordingly, a better "zero time" might be the time of the initial addition of the mixed cold slag (as oxide components). From "start of cold slag addition" to the first sample for the heats of Fig. 4 the times are: heat 73, 95 min; heat 79, 95 min; heat 86, 140 min; and heat 87, 165 min. Even on this basis

Fig. 2—Change in silicon content of metal with time for slag II at 1525°C.

Fig. 4—Decrease in sulphur in metal with time for slag II at 1525°C for heats of different initial silicon content.

there is, however, a significant improvement in desulphurization rate as the silicon in the charge increases. There also appears to be a slight improvement in the final sulphur with increased silicon content of the metal.

**Distribution of Silicon Between Slag and Metal:** There are no experimental data in the literature on the equilibrium between silicon in pig iron and silica in the slag. This equilibrium is expected to be strongly affected by temperature and by slag basicity. The latter effect is demonstrated in Figs. 1 and 2. Under the more basic slag II the equilibrium silicon content is in the vicinity of 1.2 pct, while with the more acid slag IV it is well above 4 pct. In a qualitative way the data of Hatch and Chipman and of Grant, Kalling, and Chipman show the same effect. Further research is clearly needed before quantitative conclusions regarding this equilibrium can be drawn.

### Summary

The rate of removal of sulphur from molten pig iron is affected by the silicon content of the iron. The results are interpreted as showing that silica in the slag is a sufficiently good oxidizing agent to interfere with the principal desulphurizing reactions. When sufficient silicon is present to prevent further reduction of silica the transfer of sulphur from metal to slag is extremely rapid.

The distribution of silicon between slag and metal is an important factor in desulphurization and requires further study.

# Desulphurizing Action of Titanium in Steels

by W. P. Fishel, William P. Roe, and James F. Ellis

This paper reports the distribution of sulphur between iron and titanium in Fe-Ti-S alloys and in Fe-Ti-C-S alloys. The compound TiS was found, which exists as a separate phase at temperatures below 1200°C. Titanium in steels reacts with sulphur in preference to carbon.

THE general relationship between sulphides and oxides suggests that titanium should form a sulphide having properties similar to those of titanium oxide. Specifically, titanium should form a sulphide having a high melting point, indicating a stable compound of low solubility in iron. In order for titanium to function as a desulphurizer or sulphur-fixing agent, it must form a stable sulphide. In order for titanium to be useful in steels as a sulphur-fixing agent, it must react with sulphur in preference to carbon; and to prevent red shortness, the sulphide formed must have solubility characteristics such that grain-boundary precipitation of a low melting phase be prevented. The terms desulphurizer and sulphur-fixing agent when used in this paper mean that titanium effectively ties up the sulphur as a stable sulphide of titanium and prevents the formation of FeS.

The partition of sulphur between iron and titanium was studied first in a series of Fe-Ti-S alloys with carbon absent, and then in similar alloys with carbon present.

It has been established<sup>1,2</sup> that titanium forms in Fe-Ti-S alloys a sulphide of undetermined composition which can be identified microscopically, and that the titanium-sulphur compound does not respond to sulphur printing. It has been suggested<sup>3</sup> that titanium acts as a sulphur-fixing agent, although little proof has been given. A report<sup>4</sup> of The Advisory Committee on Metals and Minerals summarizes the existing knowledge concerning substitutes for manganese in steels.

## Distribution of Sulphur Between Iron and Titanium with Carbon Absent

The alloys for this investigation were made by melting Armco iron, metallic titanium, and iron sulphide in alundum crucibles in an induction furnace. The titanium was added after the other ingredients had melted. In these alloys it is recognized that some TiO<sub>2</sub> is present, since the melts were made in the air and since no other deoxidizing agent was used; therefore, some of the titanium was not available for union with sulphur. Thirteen ingots were made. Ingots 2 to 8 were cast in baked-sand molds; ingots 12 and 13 were cast in metal molds;

W. P. FISHEL, Member AIME, is Professor of Metallurgy, and W. P. ROE is Graduate Student, Vanderbilt University, Nashville, Tenn. J. F. ELLIS, with the American Cast Iron Pipe Co., Birmingham, Ala., was formerly a Graduate Student, Vanderbilt University on a fellowship furnished by the American Cast Iron Pipe Co.

Discussion on this paper, TP 3085C, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, June 28, 1950; revision, Feb. 14, 1951. St. Louis Meeting, February 1951.

and ingot 9 was allowed to cool in the crucible in which it was melted. All ingots were annealed at 900°C for 3 hr and were cooled slowly in the furnace. Subsequent information indicates that this anneal had no effect upon the titanium sulphide particle size, since the sulphide does not go into solution at this temperature. The ingots as-cast were approximately 8 in. long and 3/4 in. diam. The compositions of the eight ingots and the results of the partition of sulphur are recorded in Table I.

Total titanium and total sulphur were determined by standard gravimetric methods. Sulphur, as iron sulphide, was determined by the evolution method. Boiling HCl (1:4) liberates the sulphur from iron sulphide, but leaves the titanium sulphide practically undecomposed. A complete separation of titanium sulphide and iron sulphide cannot be made by digesting these compounds in dilute HCl since titanium sulphide was found to dissolve slowly. The amount of titanium sulphide decomposed will depend upon the time in contact with the acid and upon the particle size of the sulphide. The point

| 13    | 0.154         | 0.315        | 0.52       | 0.133                            | By difference                      | 54.5                |
|       | 0.161         | 0.295        |            | 0.144                            |                                    |                     |
|       | 0.158         | 0.305        |            | 0.139                            | 0.166                              |                     |

involved is one of reaction or solution rates. Therefore, the figures representing sulphur as FeS in Table I are probably high, and those for sulphur as TiS are correspondingly low. The sulphur not liberated by HCl in the evolution flask was determined gravimetrically. This was considered to be titanium sulphide, which in this paper is represented by the formula TiS.

The percentages of sulphur in these alloys are much higher than would be found in commercial steels. They were made so intentionally in the interest of better separations. The ratio of titanium to sulphur as well as the amounts of titanium and sulphur in these alloys cover wide ranges. In alloys 2, 4, 5, 6, and 8, which were cast in sand molds, there is a gradual increase in the ratio of titanium to sulphur from 0.77 to 2.68. There is also an increase in the amount of total sulphur combined with titanium as the Ti:S ratio increases. The rapid cooling given these alloys produced finely divided particles of titanium sulphide. These small sulphide particles suffered more loss by solution during the evolution analysis with HCl than did the larger particles of alloy 9. The values given for sulphur as TiS could be too low if the samples were digested for a very long time, or too high if not digested long enough so that some FeS was left undecomposed. Considering the methods used in these analyses, it is believed that the values given for sulphur as TiS in most cases are low.

Alloy 9 was cooled slowly from the melt and was found to contain large particles of titanium sulphide. In this alloy 95.5 pct of the total sulphur was present as TiS, although the ratio of Ti:S was only 2.15. In Fig. 1 the micrographs of alloy 9 show large sulphide particles.

Alloys 12 and 13 were cast in metal molds. They had low ratios of Ti:S, yet they showed a rather high percentage of sulphur as TiS. This is probably due to better melting procedures that resulted in less oxidation of the titanium and hence left a higher percentage of titanium to react with sulphur.

From the data presented in Table I, it is evident that titanium reacts with sulphur and that the distribution of sulphur between titanium and iron varies with the amounts of titanium and sulphur present. The ability of titanium to tie up sulphur becomes more pronounced than the above data indicate, when it is remembered that part of the titanium in these alloys has united with oxygen and is not available for union with sulphur.

### Composition of Titanium Sulphide

In order to determine the composition of the sulphide formed, residues were prepared from alloy 9. This alloy was carbon-free and contained large sulphide particles. Approximately 300 g of turnings were taken from this alloy and were treated with 1:4 HCl at room temperature in a flask from which air was excluded. After all visible action had ceased, the acid was siphoned off and fresh acid added. This process was continued for six weeks. At this time no noticeable action accompanied the addition of fresh acid. A finely-divided, black residue remained which was washed several times with distilled water and allowed to settle. The same procedure then was carried out with absolute alcohol. The alcohol suspension of the residue was centrifuged; only the heavier portion of the residue was collected. At this point the residue appeared bronze in color. The alcohol was poured off, and the last

Upper—Fe-Ti-S, unetched. Particles of titanium sulphide and boundary segregation. X160.  
Lower—Unetched. Particles of titanium sulphide. X650.

traces were removed by repeated ether treatments. The ether was removed by centrifuging and evaporation; a finely-divided, black powder remained. This residue was nonmagnetic, and appeared stable in air.

This residue was analyzed and gave the following results: Ti, 59.2 pct, 59.2 pct; and S, 18.2 pct, 18.1 pct.

Approximately 20 pct of the total is unaccounted for. The amount missing is about equal to the sulphur present. The most obvious explanation is that the residue is a mixture of about equal parts of TiS and  $TiO_2$ . Any mixture of TiS and  $TiO_2$  when ignited to  $TiO_2$  would not change weight, since one sulphur (atomic wt 32.07) is replaced by two oxygens (atomic wt 16.00). This would not be true for any other sulphide of titanium or for a nitride or a carbide.

A sample of the residue was ignited to constant weight. Sulphur dioxide was evolved and a white powder resulted. The weights were as follows: weight of residue, 0.0714 g; weight after ignition, 0.0717 g; and pct Ti in the residue, 60.2 pct. The ignited residue is  $TiO_2$ . This is considered proof that the sulphide present in the alloy has the formula TiS. The slight gain in weight which occurred could be attributed to some TiN being converted to  $TiO_2$ .

**Solubility:** In order to determine the temperature at which the sulphide formed or precipitated from solid solution, which should be near the temperature at which it dissolved on heating, several heating and quenching tests were made.

Four pieces of alloy 9 were taken. One sample was held for 2 hr at each temperature listed in

Table II—Temperature and Hardness Tests for Alloy 9

| Sample Temperature, °C | Hardness before Quenching, Rockwell E | Hardness after Quenching, Rockwell E |
|------------------------|---------------------------------------|--------------------------------------|

| 1200                   | 48                                    | 93                                   |
| 1250                   | 48                                    | 93                                   |

Table II and then quenched in water. Evidently the TiS did not dissolve at 1000°C, but did dissolve to some extent at 1100°C. This conclusion is confirmed by the microstructure. By a comparison of the structure before and after annealing, it was observed that the large sulphide particles had broken down to some extent at the higher temperatures into smaller ones, and that some grain-boundary precipitation had taken place.

#### Distribution of Sulphur between Titanium and Iron with Carbon Present

For this study five alloys were made exactly as before with the exception that carbon was added as lump graphite. The carbon was added immediately after the iron was molten and before the addition of titanium. The addition of carbon produced sounder ingots due to the deoxidation of the metal, this in turn allowed for less oxidation of the alloying element so that titanium could exert its full effect as a desulphurizing agent. The melts were poured into metal molds and were annealed at 900°C.

The alloys were analyzed for total titanium, total sulphur, total carbon, sulphur as FeS, sulphur as TiS, and carbon as TiC. Since TiC is insoluble in HCl, a good approximation of the amount of titanium united with carbon may be had by dissolving the steel in dilute HCl, filtering the insoluble residue in a combustion thimble, and igniting to CO<sub>2</sub>. The residue from HCl contains all of the TiC present in the steel and some free carbon resulting

\* These values are too high due to free carbon from Fe<sub>3</sub>C.

† Results by analysis.

from the action of the acid upon Fe<sub>3</sub>C. The values for carbon as TiC are therefore a little higher than the true values.

Table III gives the compositions of the five alloys and the compounds found in them. There is more carbon present than is required to react with all the titanium. Despite the presence of excess carbon, the data show that a considerable amount of titanium sulphide is formed. For example, in alloy D over half the sulphur is present as titanium sulphide, even though the Ti:S ratio is only 1.39, and in spite of the presence of twice as much carbon as is needed to react with all the titanium present. Some of the values presented in Table III do not agree very well among themselves. If the amount of titanium as carbide and the amount as sulphide is calculated, the total is greater than the total titanium listed. Part of this discrepancy is due to the known high values of C as TiC, col. VI, part to the inability to make a clean separation between FeS and TiS, and the remainder to analytical errors. In spite of the inexactness of the figures presented, Table III serves to give a qualitative picture of the distribution of sulphur between titanium and iron in alloys containing carbon. In all these alloys, with the exception of alloy A, over half the total sulphur is present as HCl-insoluble titanium sulphide. Very little titanium carbide is present. The values for C as TiC, col. VI, multiplied by 4 gives the titanium as TiC. It will be noted that the Ti:S ratios in these alloys are below 1.5, the ratio for TiS; hence there is insufficient titanium present to react with all the sulphur. At this stage of the research the identity of the titanium sulphide was not known; otherwise, alloys with higher ratios would have been used. Later work by another investigator shows that if the Ti:S ratio is above 2, nearly all the sulphur is present as TiS.<sup>5</sup>

These alloys were examined microscopically. All contained pearlite and particles of titanium sulphide.

From the above it would appear that titanium in steels reacts with sulphur in preference to carbon, and that titanium tends to tie up sulphur as a sulphide, thus inhibiting the formation of iron sulphide.

One ingot containing 0.5 pct C, 0.05 pct S, 0.15 pct Ti, but no manganese was hot rolled to a thin strip. Several ingots of similar compositions were hot forged. The hot working properties were normal.

#### Conclusions

1—It has been shown that titanium will react with sulphur in steels containing carbon to form TiS, insoluble in  $\gamma$  iron below 1000°C; and that titanium reacts with sulphur in preference to carbon.

2—Titanium can replace manganese as a sulphur-getter in steels.

# Grain Structure of Aluminum-Killed, Low Carbon Steel Sheets

by R. L. Solter and C. W. Beattie

**A**LUMINUM-KILLED, low carbon steel sheets are used extensively for severe deep drawing and other difficult forming operations. They usually, but not always, have a characteristic grain structure in which the grains are elongated both in the lengthwise and in the transverse direction. As described by Burns and McCabe,<sup>1</sup> a typical grain in the plane of the sheet has its two axes in that plane from  $1\frac{1}{2}$  to 4 times as long as the axis normal to the plane of the sheet. Rickett, Kalin, and MacKenzie<sup>2</sup> have also reported on the recrystallization behavior of such steel. The contrast in grain structures of fully processed sheets of aluminum-killed and rimmed steel is illustrated by Figs. 1 and 2. The elongated grain structure of the aluminum-killed sheet is not developed on all heats or lots of this metal, and studies of the factors controlling and influencing its formation are reported in this paper.

Jeffries and Archer<sup>3</sup> state that unstrained grains are normally equiaxed, but exceptions are common. For example, if a metal containing a material mechanically obstructing grain growth is subjected to considerable working followed by thorough annealing, it may exhibit grains consistently elongated in the direction of working. Our experiments demonstrate that aluminum-killed, low carbon steel is such a metal, and that the substance mechanically obstructing grain growth is aluminum nitride. The effectiveness of aluminum nitride in inhibiting grain growth has been found to be influenced by the degree of cold reduction, the rate of heating in annealing, the thermal history of the sample before cold reduction, and the residual aluminum content. A correlation between grain shape and austenitic grain coarsening temperature also was indicated and additional experiments demonstrated that aluminum nitride is also the principal cause for the fine grain characteristic of aluminum-killed steels.

## Manufacture

In conventional practice, aluminum-killed sheet steel is manufactured from a low carbon steel containing approximately 0.02 to 0.07 pct residual (HCl-soluble) Al. With the exception of certain samples containing greater or lesser amounts of aluminum, the steels used in these investigations were within the following composition range: C, 0.03 to 0.06 pct; Mn, 0.28 to 0.38; S, 0.017 to 0.032; Al, 0.03 to 0.06; P, <0.01; and Si, <0.01.

Properly heated ingots are rolled to slabs about 4 in. thick. After surface conditioning, the slabs are reheated to about 2300°F and hot rolled continuously to strip about 1/10 in. thick. The strip rolling

Fig. 2—Grain structure of rimmed steel drawing sheet. X100.

is completed at a temperature of 1550°F or higher, and the strip is coiled, usually at a temperature near the lower critical transformation. After cooling, the strip is pickled to remove oxide, cold reduced 40 to 70 pct to final thickness, then annealed to 1250° to 1350°F in 20 to 80 ton charges, the size of which results in slow heating and cooling rates.

## Effect of Cold Reduction

According to Sachs and Van Horn,<sup>4</sup> the deformations of the individual grains in rolling are similar to those of the total volume. Thus individual grains would elongate in rolling according to the amount of cold reduction imposed. This is true theoretically, but as cold reduction increases the individual grains tend to fragment, and measured grain elongations become less than theoretical. The amount of grain elongation may be described by a numerical rating based on grain counts made by the intercept method. Specimens are polished normal to the plane of the sheet, with the polished surface extending parallel to the rolling direction.

After etching, grain intercepts are counted along a 50 mm line on a micrograph of suitable magnification. In random locations parallel to the plane of the sample 20 counts are made and 20 are made in the thickness direction of the sample. The average count in the thickness direction divided by the average count parallel to the plane of the sample gives a numerical rating of the grain shape called grain elongation. For example, a grain elongation of 2.00 means that the average grain is twice as long as it is thick. The average of both counts may be converted to grains per sq mm by a nomograph relating intercept counts and grain count. By the same procedure the grain elongation in the plane of the sheet but transverse to the rolling direction may be determined, using transverse metallographic samples.

A comparison of theoretical and measured grain elongation was obtained on an aluminum-killed

Fig. 3—Relative grain dimensions and shape in the plane of a material cold reduced only and of a duplicate material cold reduced and annealed at 1340°F. Samples were polished parallel to the rolling direction. Numbers within rectangles are grain elongation rating.

steel that had been hot rolled and then cold reduced various amounts. This steel contained 0.046 pct C, 0.33 pct Mn, 0.026 pct S, and 0.034 pct residual Al. Cold-reduced specimens were annealed at 1340°F and grain elongations were measured on the annealed materials. This comparison is given in Table I. Measurements were impossible on specimens cold reduced 80 and 90 pct because of the extreme distortion, but it seems probable that grain elongations were considerably less than the theoretical value.

Values in Table I show that, as cold reduction increased, fragmentation of individual grains occurred and the measured elongation was considerably less than was calculated. The amount of grain elongation measured after annealing was less than after cold reduction, consequently the elongation imposed by cold work was only partially retained after annealing, indicating that any mechanical obstruction to grain growth was not completely effective. Relative grain sizes and shapes of an individual material in the cold-reduced and the cold-reduced and annealed condition are shown by appropriately dimensioned rectangles in Fig. 3. The larger grain size of annealed specimens of this material is further evidence that mechanical obstruction did not completely inhibit grain growth.

This illustration is an individual case representative of one material. Measurements of 14 other samples gave a diversity of results. No two reacted

exactly alike to the influence of cold reduction. Such inconsistency indicated that factors other than the amount of cold reduction influenced grain size and shape. However, the average values of grain elongation and grain count show that a definite relationship exists with variations in cold reduction, as illustrated in Fig. 4. Both grain elongation and grain count increased with increasing cold reduction with a noticeable change in rate of increase above 60 pct. Grain elongation and grain size also appear to be related when compared at a given cold reduction. A group of 124 materials was cold reduced 60 pct and annealed at 1340°F. Grain counts and grain elongations were determined. These data were listed in order of decreasing grain elongations and grouped in ten approximately equal groups. The average grain elongation and grain count was determined for each group and plotted in Fig. 5. This curve demonstrates that for a given amount of cold reduction a sample with a larger grain count was likely to have less grain elongation than one with a smaller grain count. Thus, the final grain structure becomes finer and more elongated as cold reduction increases, but the amount of grain elongation developed by a given amount of cold reduction is more if the grain size is larger.

### Effect of Variations in Heating to the Annealing Temperature

Three hot-rolled strip materials were secured, each from a different heat, as given in Table II. These materials were cold reduced 60 pct and annealed with two variations in heating rate. Variation 1 consisted of heating the samples to 1340°F in ½ hr. Variation 2 consisted of heating the samples

Table II. Composition of Materials, Pct

| Element     | Material 1 | Material 2 | Material 3 |
|-------------|------------|------------|------------|
| C           | 0.041      | 0.040      | 0.039      |
| Mn          | 0.33       | 0.26       | 0.32       |
| S           | 0.019      | 0.020      | 0.020      |
| Residual Al | 0.043      | 0.038      | 0.042      |

to 1340°F in 22 hr using a uniform rate of 25°F per hr above 800°F. In both instances samples were held at temperature 4 hr and cooled 25°F per hr to about 500°F before removing from the furnace. Grain elongation and grain counts resulting from these treatments are shown in Table III. Grain structures of Material 2 are shown in Fig. 6. These data show that fast heating resulted in a finer grain with less elongation than slow heating.

The same three materials were given a 2 hr heat treatment at temperatures of 300° to 1100°F prior to annealing with heating Variation 1. Heating for 2 hr at 700° to 1100°F caused the final grain structure to be coarser and more elongated than would normally have been expected from heating Variation 1. This is illustrated in Fig. 7.

### Determination of Aluminum Nitride

These and other studies led to the belief that the observed recrystallization behavior of aluminum-killed steel is influenced principally by the precipitation of a constituent during the heating portion of the annealing cycle. It was long suspected that this constituent was aluminum nitride. H. F. Beeghly<sup>6</sup> recently reported a sound and reproducible method for determining this compound, and demonstrated that the amount present varied with the heat treatment received by the sample before analysis. Hot-rolled, aluminum-killed steel samples were shown to contain different amounts of nitrogen as alu-

Fig. 4—Relationship of grain count and grain elongation of samples cold reduced and annealed at 1340°F.

minum nitride if reheated 1 hr at various temperatures. His data are plotted in Fig. 8. As hot-rolled, the amount of nitrogen combined as aluminum nitride is low, but as the annealing temperature increased, the amount increased to a maximum in a temperature range from about 1300° to 1800°F. At temperatures above 1800°F, the amount decreased until at about 2350°F no more was present than in the original hot-rolled bar. This indicates that aluminum nitride is held in supersaturated solution in hot-rolled samples. If the samples are reheated the aluminum nitride precipitates up to a maximum amount at 1300° to 1800°F and at higher temperatures it redissolves.

This precipitation and re-solution of aluminum nitride is believed to be responsible for the behavior of aluminum-killed steels both with respect to the grain shape of the cold-reduced and annealed sheets and to the austenitic grain refining characteristic of such steels, and has been demonstrated by the following experimental procedures.

#### Effect of Thermal History before Cold Reduction

In considering the effect of thermal history on grain shape it should be understood that the grain shape referred to in the following discussion is that of the final cold-reduced and annealed product, even though the heat treatments described may have been performed before cold reduction and final annealing. Twelve samples of hot-rolled strip with the normal chemistry range were secured and reheated; one group to 1800°F and air cooled, a duplicate group to 1800°F and furnace cooled, a third group to 2100°F and air cooled, and a fourth group to 2100°F and furnace cooled. Following heat treatment the samples were cold reduced 60 pct and annealed at 1340°F. After annealing the structures were as shown in Fig. 9. All had equiaxed grain structures except those heated to 2100°F and air cooled before cold reduction. This group had the elongated grain

Fig. 6—Effect of heating rate during annealing of cold-reduced samples. X100.

Fig. 5—Relationship of grain elongation to grain count of samples cold reduced 60 pct and annealed at 1340°F.

shape as would be expected for this type of steel. The grain structures of samples heated to 2100°F were coarse as compared to those heated to 1800°F, showing that the coarsening temperature was reached or exceeded by the 2100°F treatment.

Heating to 2100°F and air cooling is believed to have caused a re-solution of aluminum nitride and a retention of the compound in supersaturated solid solution. In the final anneal after cold reduction, the aluminum nitride precipitated in the normal manner and resulted in an elongated grain structure. In the other heat treatments, precipitation of aluminum nitride occurred in the strip before cold reduction. This behavior was demonstrated in a slightly different manner by heat treatments performed on hot-rolled strip. Five different hot-rolled strip materials were used. The nitrogen content as aluminum nitride and the total nitrogen content (includes iron nitride, etc.) were determined on the hot-rolled

strip: 1—as hot rolled, 2—as hot rolled, cold reduced, and annealed at 1340°F, 3—as air cooled from 2100°F, and 4—as furnace cooled from 2100°F. Nitrogen contents as aluminum nitride were determined by the Beeghly method<sup>6</sup> and total nitrogen contents by another Beeghly method.<sup>6</sup> The results are listed in Table IV.

The nitrogen determinations of Group 1 for the “as hot-rolled” condition show the low nitrogen as

Fig. 7—Grain structures resulting from annealing samples with fast heating. X100.

Fig. 8—Aluminum-killed steel hot rolled and reheated 1 hr at various temperatures (after Beeghly).

aluminum-nitride values which are characteristic of rapid cooling from above the critical temperature range. Group 2 for the cold-reduced and annealed condition shows that practically all of the nitrogen present has precipitated as aluminum-nitride during annealing after cold reduction. Group 3 shows that air cooling from above the coarsening temperature results in even less nitrogen as aluminum-nitride than in the hot-rolled condition. On the other hand, furnace cooling from above the coarsening temperature, Group 4, resulted in considerable pick-up of total nitrogen from the air atmosphere and the precipitation of most of it as aluminum-nitride. Samples were wrapped in soft steel sheets to minimize this but aluminum-bearing steels display a great affinity for nitrogen.

In another experiment two specimens of roughing mill stock  $\frac{3}{4}$  in. thick were heated to 2100°F; one was air cooled to room temperature, the other was furnace cooled. Both were cold reduced 45 pct and annealed at 1340°F. This gave two kinds of material; the air-cooled sample in which precipitation took place during annealing after cold reduction and the furnace-cooled sample in which precipitation occurred before cold reduction. Charpy impact speci-

mens cut parallel to the rolling direction and notched at one surface were broken at a series of temperatures with results listed in Table V. Material with the elongated grain shape had considerably less impact resistance than the same material with equiaxed grain shape. Precipitation of aluminum nitride at the boundaries of the elongated grains in the air-cooled sample, creating planes of weakness, could account for the reduced impact resistance. An equal amount of precipitate in the boundaries of the equiaxed grains of the furnace-cooled sample would not have the same effect on the impact resistance.

#### Effect of Cooling Rate and Heat Treatment

The effect of retarding the cooling rate after finishing the hot-rolled strip at 1550°F was studied, together with the effect of reheating such strip after air cooling or coil cooling. Strip hot rolled and held, or reheated and held at constant temperature for a certain minimum time was no longer capable of producing the elongated grain shape after cold reduction and box annealing, but yielded equiaxed grain structures. The higher the holding temperature, the less was the time required to effect the change. The minimum times required to change grain shape from elongated to equiaxed as determined on one lot of material are shown in Fig. 10. The reheating time was least for mill-rolled and coiled strip, indicating that precipitation was partially completed during coil cooling.

The effect of reheating hot-rolled strip on the nitrogen content as aluminum nitride was determined on the same five materials shown in Table IV. These materials were subjected to reheating times of 30, 60, and 100 min at 1250°F. Results of chemical analyses before cold reduction and annealing and the microstructure after cold reduction and annealing are listed in Table VI. Tests on hot-rolled only (no reheating) samples are included for comparison. The data illustrate progressive precipitation of aluminum nitride with increase in holding time. It appears that after a sufficient length of time the amount of aluminum nitride remaining in solid solution was no longer influential in obstructing development of equiaxed grains after cold reduction and annealing.

#### Grain Shape Related to Grain Coarsening Temperature

Two groups of six samples each were selected on the basis of their cold-reduced and annealed grain structure. The Group 1 samples had a grain size of A.S.T.M. 6 and grain elongations varying from 2.4 to 3.1. The Group 2 samples had a grain size of A.S.T.M. 8 and grain elongations of 1.3 to 2.0. Both groups were within the following composition

a—1800°F and air cooled.

b—1800°F and furnace cooled.

c—2100°F and air cooled.

d—2100°F and furnace cooled.

Fig. 9—Grain structures of cold-reduced annealed samples heated before cold reduction.

| 5        | 0.042                     | 0.33 | 0.020 | 0.043          | 0.0053                    | 0.0007 | 0.0056                                           | 0.0051 | 0.0046                                | 0.0002 | 0.016                                     | 0.014  |

ranges: 0.031 to 0.057 pct C, 0.29 to 0.38 pct Mn, 0.017 to 0.028 pct S, and 0.037 to 0.061 pct residual (HCl soluble) Al.

When samples of the hot-rolled strip from which the 12 sheet samples had been processed were heated to 1800°F for 20 min and air cooled, all were fine grained. When heated to 1950°F for 20 min and air cooled only the six Group 2 samples were uniformly fine grained. Group 1 samples had mixed grain structures containing both coarse and fine grains. After heating to 2100°F for 20 min and air cooling, all Group 1 and 2 samples were uniformly coarse grained. The samples having larger, more elongated grains in the cold-reduced and annealed condition also coarsened at a lower temperature on heating in the austenite range.

#### Nitrogen Content Related to Grain Coarsening

The relationship of nitrogen content as aluminum nitride to grain coarsening was studied using the five hot-rolled strip materials shown in Tables IV and V. These were heated to 1700°, 1800°, 1900°, 2000°, and 2100°F and air-cooled. Microstructure and nitrogen content as aluminum nitride are given in Table VII. These data show that there is a relationship between nitrogen content as aluminum nitride and grain coarsening. Aluminum-killed steels coarsen rapidly above a certain minimum temperature, unlike rimmed steels which coarsen progressively as temperature is raised above the transformation range. Coincident with the grain growth, which takes place between 1900° and 2000°F, there is a drop in nitrogen content as aluminum nitride indicating that the precipitate is redissolved, removing the obstruction to grain growth. At 2100°F the undissolved aluminum nitride is extremely low and the materials are fully coarsened.

#### Effect of Variation in Aluminum Content

Ingots from two heats of low carbon, aluminum-killed steel were alloyed to provide a range of from 0.015 to 0.20 pct residual (HCl soluble) Al. Samples of the hot-rolled strip were cold reduced 60 pct and

annealed at 1340°F. Final grain shape, residual aluminum, and nitrogen contents as aluminum nitride are shown in Table VIII. These data show that within the range 0.034 to 0.066 pct residual Al (1B, 2A, 2B, 2C) elongated grain structure resulted after cold reducing and box annealing. The behavior of samples outside this range of residual aluminum content resulted in intermediate or equiaxed grain structures. Samples 1C, 1D, and 1E had equiaxed grains. Note that the available aluminum nitride was precipitated before cold reduction, thus leaving none available to precipitate during annealing.

However, samples 2D and 2E, with final grain structures respectively intermediate and equiaxed, did not precipitate aluminum nitride before cold reduction despite their high residual aluminum content. Reasons for this behavior contrasted to that of samples 1C, 1D, and 1E are not certain, but there are two probabilities. The coiling temperature of the hot-rolled strip may have been lower on Heat 2 than Heat 1, thereby affording less chance for the AlN to come out of solution during cooling. Second, samples 2D and 2E as well as others from Heat 2 had unusually low nitrogen content as aluminum nitride after cold reduction and annealing. The small amount precipitated during annealing in the presence of the higher aluminum content may have been ineffective in controlling grain shape. Sample 1A had a low aluminum content and a normal nitrogen content as aluminum nitride. The grain structure was intermediate between elongated and equiaxed shape, indicating that too low an aluminum content also tended to make the precipitate less effective in controlling grain shape.

Thus the optimum range for producing elongated grain structures was from somewhat above 0.015 to about 0.066 pct residual Al. This range of aluminum content is also of interest in austenite grain coarsening studies because, as shown by Washburn,<sup>7</sup> the propensity for aluminum-killed steels to be fine grained is maximum within this same range and diminishes with increased aluminum. This further indicates that the two phenomena are related, be-

cause both fine grain behavior and grain elongation characteristics diminish outside this range of aluminum content.

### Conclusions

The preceding experiments demonstrate that all sheets of low carbon, aluminum-killed steel composition did not react uniformly to the conditions imposed. However, certain conditions were more conducive to the elongated grain shape than others. These were the conditions:

- 1—A residual aluminum content somewhat above 0.015 to about 0.066 pct.
- 2—Heating the hot-rolled strip to above the coarsening temperature and cooling relatively fast.
- 3—Coiling the hot-rolled strip near the lower critical temperature.
- 4—Cold reducing the hot-rolled strip without preliminary reheating.
- 5—Cold reducing the hot-rolled strip more than 30 pct.

6—Annealing after cold reduction using: a—A relatively slow heating rate, or b—A heat treatment at 700° to 1100°F preliminary to the final anneal.

This behavior can be explained by the following hypothesis: A supersaturated solid solution of aluminum nitride in steel is created by heating the material above the coarsening temperature and rapidly cooling to room temperature. This supersaturated solid is cold reduced. During the heating portion of the conventional annealing cycle, precipitation of aluminum nitride occurs to a major extent before the recrystallization temperature is reached. The development of more equiaxed grain structures by fast heating indicates that in this case recrystallization and grain growth takes place before precipitation.

This precipitation during slow heating takes place principally at preferred locations such as boundaries of grains elongated by cold reduction. The pre-

cipitate forms a mechanical obstruction to normal recrystallization and results in an elongated grain shape retaining part of the elongation imposed by cold reduction. When the supersaturated solid solution is heated before cold reduction, the nitride is believed to precipitate in a manner which does not influence the final grain shape. After such heating the precipitate resides in the hot-rolled strip grain boundaries and remains out of solution during cold reduction and annealing. After such material has been cold reduced, recrystallization during annealing results in an equiaxed grain structure.

The effectiveness of the compound in controlling grain shape is most pronounced in the same limited range of residual aluminum content most favorable for promoting fine grained behavior of the austenite. When heated, a re-solution of the compound takes place only at or above the austenite grain coarsening temperature. It appears that aluminum nitride

not only inhibits development of equiaxed grain structure of cold-reduced ferrite, but is also largely responsible for the fine grained behavior of aluminum-killed steel in the austenite range; in the former case when the steel is supersaturated with respect to aluminum nitride prior to cold reduction and heated slowly for annealing, and in the latter case when the aluminum nitride is precipitated during heating to the austenitizing temperature.

### Acknowledgment

The authors wish to express their appreciation to the Armco Steel Corp. for permission to publish this paper. They gratefully acknowledge the helpful advice and counsel of R. S. Burns and R. H. Heyer in its preparation and the contributions made by C. E. Bussert, G. E. Koepfel, and other members of the Armco Research Laboratories in carrying out some of the suggested investigations.

# Isothermal Formation of Martensite at Subzero Temperatures in a High Chromium Steel

by S. C. Das Gupta and B. S. Lement

Isothermal formation of martensite occurs in the range of  $-65^{\circ}$  to  $-197^{\circ}\text{C}$  and is always preceded by some athermal transformation. By rapid cooling the isothermal, but not the athermal, component of transformation can be suppressed. Stabilization against isothermal transformation can be induced by cycling from below  $M_s$  to room temperature.

**A**LTHOUGH the transformation of austenite to martensite is generally believed to occur only on cooling, recent evidence indicates that this reaction can also occur at constant temperature. Isothermal formation of martensite was observed in tool steel by Fletcher, Averbach, and Cohen.<sup>1,2</sup> They found that the hardening reaction that occurs during the quenching of a plain carbon or low carbon alloy tool steel does not stop immediately when room temperature is reached; instead austenite continues

to transform at room temperature although at a decreasing rate. Since only a small amount of austenite transforms in this fashion, isothermal formation of martensite was considered to be merely a "tailing off" effect of the main hardening reaction.

Another point of view was advanced by Kurdjumov and Maksimova<sup>3,4</sup> who reported that the austenite-martensite reaction could be suppressed by rapid cooling of a 6 pct Mn-0.6 pct C steel in liquid nitrogen and that as much as 25 pct martensite could be formed by reheating to and holding at subzero temperatures above that of liquid nitrogen. These investigators came to the conclusion that martensite is thermally nucleated at certain special regions in the austenite and subsequently grows to observable dimensions.

Isothermal transformation of austenite to martensite was cited by Fisher, Hollomon, and Turnbull<sup>5</sup> as evidence supporting another nucleation and growth theory of martensite formation. According

Fig. 1—Subzero furnace.

to this theory, at certain subzero temperatures the rate of growth of athermally formed martensite nuclei becomes slow enough so that isothermal transformation is measurable. This point of view was disputed by Kulin and Cohen<sup>6</sup> who showed that transformation of austenite to martensite is possible at a temperature as low as  $-266^{\circ}\text{C}$ , where a negligible rate of growth is predicted by the nucleation and growth theory.<sup>5</sup>

A new mechanism involving nucleation of strain embryos has been advanced by Cohen, Machlin, and Paranjpe<sup>7</sup> to explain the austenite-martensite transformation. According to these investigators isothermal transformation is due to temperature fluctuations which supply sufficient energy to complete the "shearing over" to martensite of strain embryos initially below a critical "shear" angle.

The present investigation was carried out to obtain additional information with respect to isothermal transformation at subzero temperatures. In order to check whether the phenomena reported by Kurdjumov and Maksimova<sup>8</sup> are of general occurrence, a high chromium steel having essentially the same transformation range as reported for their manganese steel was selected for this investigation.

### Experimental Details

**Chemical Composition:** The chemical composition of the steel investigated is as follows: C, 0.73; Mn, 0.28; Si, 0.20; S, 0.02; P, 0.02; and Cr, 14.84. This steel is from the identical heat used in the investigation of Klier and Troiano<sup>9</sup> to determine the effect of chromium and carbon contents on the  $M_s$  temperature.

**Austenitizing Treatment:** Specimens approximately  $1/16 \times 1/8 \times 1/4$  in. were sealed in an evacuated quartz tube and then austenitized for 2 hr at  $1275^{\circ}\text{C} \pm 5^{\circ}\text{C}$  in a platinum-rhodium wound tube furnace. This treatment which resulted in a grain size of A.S.T.M. No. 1-2 was selected on the basis of obtaining complete carbide solution.

Table I. Time Required to Reach Temperature

| Operation    | Initial Temperature, $^{\circ}\text{C}$ | Final Temperature, $^{\circ}\text{C}$ | Medium at Final Temperature | Time Required, Sec |
|--------------|-----------------------------------------|---------------------------------------|-----------------------------|--------------------|
| Subcooling   | 5                                       | -60 - -150                            | Organic liquid              | 18 $\pm$ 3         |
| Subcooling   | 5                                       | -197                                  | Liquid nitrogen             | 10 $\pm$ 3         |
| Up-quenching | -197                                    | -150 - -40                            | Organic liquid              | 15 $\pm$ 3         |
| Up-quenching | -197                                    | 20                                    | Water                       | less than 3        |

**Quenching Procedure:** Quenching was carried out in a 10 pct brine solution maintained at a temperature of  $5^{\circ}\text{C}$ . The quartz tube containing about five specimens was quickly transferred from the austenitizing furnace to the brine quench, and the tube was broken immediately. The breaking into a vacuum resulted in an efficient quenching action since 100 pct austenite was retained at  $5^{\circ}\text{C}$ .

**Subzero Cooling:** After quenching the specimens were placed in a subzero furnace maintained within  $\pm 1^{\circ}\text{C}$  of a selected temperature in the range of  $-60^{\circ}$  to  $-150^{\circ}\text{C}$ . The details of the subzero furnace are shown in Fig. 1. This furnace operates on the same principle as an ordinary resistance wound furnace; however, instead of room temperature at the outside of the furnace, liquid nitrogen in a thermos flask is used to provide an outside temperature of  $-197^{\circ}\text{C}$ . The inner pyrex tube contains an organic liquid mixture consisting of 75 pct petroleum ether and 25 pct methylcyclohexane, which has a freezing point of just under  $-150^{\circ}\text{C}$ . Temperature uniformity as well as a rapid rate of either subcooling or up-quenching is brought about by means of a stirrer. The times required for the centers of  $1/16 \times 1/8 \times 1/4$  in. specimens to reach within  $1^{\circ}\text{C}$  of selected temperatures using the subzero furnace were found to be as given in Table I. According to these results, subcooling in liquid nitrogen at  $-197^{\circ}\text{C}$  is more rapid than in the organic liquid maintained as low as  $-150^{\circ}\text{C}$ ; and up-quenching in water at  $20^{\circ}\text{C}$  is more rapid than in the organic liquid maintained as high as  $-40^{\circ}\text{C}$ .

**Metallographic Analysis:** Quantitative determination of the extent of transformation to martensite was carried out by the method of lineal analysis developed by Howard and Cohen.<sup>8</sup> The precision of measurement is estimated to be  $\pm 1$  pct martensite for the amounts of this constituent encountered in the present investigation. After a subzero treatment, specimens were mounted in bakelite, metallographically polished, and etched with a modified Vilella's reagent. Although the martensite plates are not darkened by this procedure, the boundaries become sufficiently sharp so that no difficulty is experienced in distinguishing between the two constituents.

It was found that the amount of martensite increases with distance below the surface of transformed specimens and reaches an approximately constant value at a depth of about 0.010 in. It is believed that this effect is due to residual stress set up on quenching from  $1275^{\circ}$  to  $5^{\circ}\text{C}$ . Since no transformation occurs during such quenching, it would be expected that due to differences in cooling rate compressive stresses are set up at the surface and tensional stresses at the interior. On subsequent cooling to subzero temperatures, the transformation is apparently hindered by the presence of compressive stresses at the surface. The amounts of martensite reported in this investigation were measured at a depth of 0.020 in. and are representative of the interiors of the specimens where tensional stresses apparently do not cause any appreciable variation.

### Results

**Martensite Formed on Cooling:** The amount of martensite formed on cooling is shown in Fig. 2. In this experiment a specimen was kept in the subzero furnace just long enough to reach the temperature of the organic liquid bath and then up-quenched

Fig. 2—Amount of martensite formed as a function of temperature in a 15 pct Cr-0.7 pct C steel austenitized 2 hr at 1275°C.

immediately to 20°C in water. The  $M_s$  temperature was found to be  $-65^\circ\text{C} \pm 5^\circ\text{C}$ . This is in agreement with the results of Klier and Troiano<sup>8</sup> who found a  $M_s$  temperature of between  $-38^\circ$  and  $-77^\circ\text{C}$  for  $\frac{1}{4} \times \frac{1}{4} \times \frac{1}{4}$  in. specimens heat treated in a similar fashion. However, although these investigators report that holding 1 hr at room temperature prior to subcooling lowers  $M_s$  to below  $-77^\circ\text{C}$ , this was not confirmed. In fact, reheating as-quenched specimens to a series of temperatures as high as 500°C for 1 hr prior to subzero cooling likewise was not found to have any appreciable effect on the  $M_s$  temperature.

On cooling below the  $M_s$  temperature the amount of martensite increases progressively and apparently reaches a maximum at about  $-150^\circ\text{C}$ , which is the lowest temperature that can be obtained with the organic liquid used. However, specimens cooled to the temperature of liquid nitrogen ( $-197^\circ\text{C}$ ) were found to contain about 7 pct less martensite than specimens cooled to  $-150^\circ\text{C}$ . This anomaly indicates that the austenite-martensite reaction in this steel can be partially suppressed by rapid cooling in liquid nitrogen. There appears to be a limit to the extent of this suppression since decreasing the specimen thickness from 0.070 to 0.020 in., which should effectively increase the cooling rate, does not change the amount of martensite formed on subcooling in liquid nitrogen to  $-197^\circ\text{C}$ . In fact, a thickness of 0.010 in., which is commensurate with the austenite grain size, actually results in a small increase in the amount of martensite at  $-197^\circ\text{C}$ . Possibly, this increase is due to the greater freedom from constraints to local change of shape associated with transformation in a single crystal of austenite as compared to polycrystalline austenite.

On the basis of these experiments it appears that subcooling in the organic liquid to temperatures above  $-150^\circ\text{C}$  does not result in purely athermal\* martensite but rather a combination of athermal and anisothermal\*\* martensite. The possible extent of anisothermal transformation is indicated by the extrapolation from  $-100^\circ$  to  $-197^\circ\text{C}$  in Fig. 2. By rapid subcooling it appears possible to suppress the anisothermal transformation but not the athermal transformation. Since the transformation occurs anisothermally, which means that it is time-dependent as

Fig. 3—Isothermal formation of martensite at various subzero temperatures in a 15 pct Cr-0.7 pct C steel austenitized 2 hr at 1275°C.

well as temperature-dependent, isothermal† transformation would also be expected to occur.

**Isothermal Martensite Formation:** The amount of martensite formed as a function of time at a series of constant subzero temperatures is shown in Fig. 3. Isothermal transformation of austenite to martensite was found to occur at temperatures ranging from  $-70^\circ$  to  $-197^\circ\text{C}$ . The rate of isothermal transformation decreases with time and becomes very slow after about 0.05 hr at all temperatures. The observable initial rate of isothermal transformation increases with decreasing temperature, reaches a maximum at about  $-110^\circ\text{C}$ , and progressively decreases below this temperature. If the amount of martensite is plotted against log time as in Fig. 4, the course of the reaction can apparently be represented by a straight line plot after about 0.01 hr.

Isothermal formation of martensite was found to occur as low as  $-197^\circ\text{C}$  and as much as 14 pct martensite forms after 24 hr at this temperature. This is shown by a series of micrographs in Fig. 5. It was observed that isothermal transformation occurs

Fig. 4—Semi-log plot showing isothermal formation at various subzero temperatures in a 15 pct Cr-0.7 pct C steel austenitized 2 hr at 1275°C.

mainly by the formation of new martensite plates rather than thickening of existing plates. Except for a larger number of smaller size plates due to the partitioning effect of increased transformation, the appearance of martensite formed isothermally was found to be the same as that formed athermally.

Holding as-quenched specimens for 1 hr at  $20^\circ\text{C}$  prior to cooling to subzero temperatures was not found to have any appreciable effect on isothermal transformation. Here again evidence of appreciable stabilization above the  $M_s$  temperature prior to cooling below the  $M_s$  temperature is lacking.

**Effect of Cycling on Isothermal Transformation:** The effects of cycling between  $20^\circ$  and  $-95^\circ\text{C}$  and between  $20^\circ$  and  $-150^\circ\text{C}$  on isothermal transformation were studied. The treatments used are illustrated in Fig. 6 and the results are given in Table II.

In treatments A, B, and C the total time at the subzero temperature is 30 min. Up-quenching to  $20^\circ\text{C}$  immediately after reaching the subzero temperature (treatment A) or after holding 3 min at the subzero temperature (treatment B) results in less martensite formation than does an uninterrupted hold at the subzero temperature (treatment C). In treatments A and B virtually complete stabilization results from up-quenching to  $20^\circ\text{C}$  and therefore the subsequent hold at the subzero temperature is ineffective in producing additional transformation. Since in both these cases some martensite is present before up-quenching to  $20^\circ\text{C}$ , these results indicate that partial transformation may be required before stabilization can occur in this steel. This suggests

\* Athermal — dependent on temperature.

\*\* Anisothermal — dependent on cooling rate.

† Isothermal — dependent on time (for a given temperature).

Zero time at  $-197^{\circ}\text{C}$ .

3 min at  $-197^{\circ}\text{C}$ .

2 hr at  $-197^{\circ}\text{C}$ .

24 hr at  $-197^{\circ}\text{C}$ .

Fig. 5—Micrographs showing isothermal transformation at  $-197^{\circ}\text{C}$  in a 15 pct Cr-0.7 pct C steel. X150.

that partial transformation stimulates subsequent isothermal transformation and that heating to  $20^{\circ}\text{C}$  wipes out the stimulating effect.

**Isothermal Transformation after Up-quenching from  $-197^{\circ}\text{C}$ :** The effect of cooling to  $-197^{\circ}\text{C}$  followed by up-quenching to and holding at various subzero temperatures is shown in Fig. 7. These experiments were carried out in order to study the effect of a constant initial amount of martensite on subsequent isothermal transformation at various temperatures. Series A specimens were held 3 min at  $-197^{\circ}\text{C}$ , which resulted in the formation of about 11 pct martensite prior to up-quenching. Series B specimens were held 2 hr at  $-197^{\circ}\text{C}$ , which resulted in the formation of about 17 pct martensite prior to up-quenching. In both series up-quenching to temperatures as high as  $-40^{\circ}\text{C}$  results in additional transformation prior to isothermal holding. The increases amount to about 6 pct martensite for series A and about 4 pct martensite for series B. The constancy of these amounts for a given series suggests that the additional transformation occurred during the short period of time the temperature passed through the range of  $-197^{\circ}\text{C}$  to about  $-150^{\circ}\text{C}$ .

At all temperatures below  $-70^{\circ}\text{C}$ , series A specimens show a higher initial rate of isothermal transformation than do series B specimens. This indicates that an increase in the initial amount of mar-

tensite from 17 to 21 pct results in a decrease in the rate of isothermal transformation at a given temperature. Since a larger initial amount of martensite would be expected to exert a greater stimulating effect on isothermal transformation, the observed decrease may be due to the greater influence of partitioning. Because of this effect, the larger the amount of initial transformation, the smaller the volume generated by nucleation of each martensite plate. Partitioning also may slow down transformation by increasing constraints to the local change of shape required by the formation of each new plate.

For both series the observable initial rate of isothermal transformation is apparently higher at  $-150^{\circ}\text{C}$  than at  $-197^{\circ}\text{C}$  and very low or zero just below the  $M_s$  temperature. For series A a maximum initial rate occurs at a temperature judged to be about  $-140^{\circ}\text{C}$ . Since these experiments were carried out keeping the initial amount of martensite constant, the observed temperature dependence of initial rate of transformation should be a direct consequence of the temperature dependence of rate of nucleation of martensite plates. This assumes that the generation of such plates, once nucleated, is practically instantaneous.

### Discussion of Results

The 15 pct Cr-0.7 pct C steel investigated was found to have a fairly definite  $M_s$  temperature of  $-65^{\circ}\text{C} \pm 5^{\circ}\text{C}$  corresponding to the particular austenitizing treatment of 2 hr at  $1275^{\circ}\text{C}$  employed. Isothermal formation of martensite was found to occur below this  $M_s$  temperature and is apparently always preceded by some athermal formation of martensite. Since it was not found possible to differentiate between athermal and isothermal martensite by metallographic examination, it appears that the mechanism of formation is essentially the same whether martensite forms on cooling or at constant tempera-

Fig. 6—Schematic representation of cyclic treatments used in investigation of stabilization effect.

Table II. Effect of Cycling on Isothermal Transformation

\* See Fig. 6.

ture. The rate of the reaction seems to be governed by the rate of nucleation of martensite plates rather than their rate of "growth" which appears practically instantaneous at all temperatures studied.

The isothermal behavior of the chromium steel was found to be similar to that of the manganese steel investigated by Kurdjumov and Maksimova.<sup>3</sup> The following points of similarity were observed. Isothermal transformation of austenite to martensite was found to occur at subzero temperatures below  $-65^{\circ}\text{C}$ . Such transformation occurs either after cooling directly to a subzero temperature below  $-65^{\circ}\text{C}$ , or after first subcooling to the temperature of liquid nitrogen ( $-197^{\circ}\text{C}$ ) and then up-quenching to the selected subzero temperature. The observable initial rate of isothermal transformation goes through a maximum with decrease in temperature below  $-65^{\circ}\text{C}$ .

It was not found possible to suppress completely the austenite-martensite reaction in the chromium steel by cooling to the temperature of liquid nitrogen ( $-197^{\circ}\text{C}$ ) as claimed by Kurdjumov and Maksimova<sup>3</sup> for their manganese steel. Confirmation of the results of Kurdjumov and Maksimova by other investigators is necessary in order to establish whether complete suppression can actually be attained. Thus far, attempts to accomplish this have proved unsuccessful<sup>6</sup> and it is probable that the reported chemical composition of the manganese steel<sup>3</sup> is erroneous.

The phenomenon of stabilization which plays an important role in isothermal transformation was not investigated by Kurdjumov and Maksimova.<sup>3</sup> This phenomenon apparently is a result of removing the stimulating effect of partial transformation by thermal means. Stabilization is nicely explained by the strain embryo theory<sup>7</sup> according to which transformation to martensite generates strain embryos that can be relaxed by stress relief even at relatively low temperatures. That partial transformation is necessary before austenite can be stabilized against further transformation on cooling was pointed out by Harris and Cohen.<sup>10</sup> The occurrence of extremely rapid stabilization resulting from interrupting the quench at room temperature prior to cooling below  $M_s$  as claimed by Klier and Troiano<sup>8</sup> was not investigated in the present work. The possible relationship of such a phenomenon to isothermal transformation merits further study.

As indicated by the results of this investigation, isothermal transformation of martensite is influenced by the temperature dependence of rate of nucleation of martensite plates, the stimulating effect of partial transformation, the geometrical effect of partitioning, and the previous history with respect to stabilization. A more detailed knowledge of these factors is required in order to judge the validity of the current theories of the mechanism of the austenite-martensite transformation.

### Summary

The following characteristics of the austenite-martensite transformation have been observed in a 15 pct Cr-0.7 pct C steel:

- 1—Partial but not complete suppression of martensite is attainable by quenching to  $-197^{\circ}$  in liquid nitrogen. The part of the transformation that is suppressible probably corresponds to the isothermal rather than the athermal component of the transformation.

- 2—Isothermal transformation occurs at subzero temperatures below  $-65^{\circ}\text{C}$  which is the  $M_s$  point

Fig. 7—Isothermal formation of martensite following up-quenching a 15 pct Cr-0.7 pct C steel from  $-197^{\circ}\text{C}$  and holding at various subzero temperatures. Austenitizing treatment consisted of 2 hr at  $1275^{\circ}\text{C}$ .

corresponding to an austenitizing treatment of 2 hr at  $1275^{\circ}\text{C}$  followed by water quenching to  $5^{\circ}\text{C}$  and then subcooling in an organic liquid.

- 3—Isothermal transformation is always preceded by some athermal transformation and occurs mainly by the formation of new plates rather than the growth of existing plates.

- 4—The observable initial rate of isothermal transformation goes through a maximum with decrease in temperature below the  $M_s$  point.

- 5—Stabilization against isothermal transformation at a given subzero temperature results from cycling between that temperature and room temperature.

# Desulphurization of Pig Iron with Pulverized Lime

by Bo Kalling, C. Danielsson, and Ottar Dragge

THE desulphurizing of pig iron has been accomplished with a number of different additions. The oldest and still most commonly used agent is soda, the extensive use of which commenced about 1925, when it was used principally for cupola furnace iron. More recent experience<sup>1</sup> seems to show that better results can be obtained with sodium hydroxide. The well-known desulphurizing properties of lime have also been exploited in different technical processes. Another material with even more powerful effect is calcium carbide.<sup>2</sup> The desulphurizing ability of manganese, when added to the ladle in sufficient quantity, should also be mentioned in this connection. During recent years increasing attention has been paid to the desulphurizing properties of metallic magnesium.<sup>3</sup> An addition of a suitable alloy of magnesium is now in use purely for the purpose of sulphur elimination.

Of the desulphurizing agents mentioned, lime is by far the cheapest, provided that the reaction can be brought about rapidly and completely. Therefore, a method that makes full use of the desulphurizing ability of lime may be able to compete with other processes. A method developed at the Domnarfvet Iron and Steel Works (Sweden) will be described, which enables pig iron to be rapidly desulphurized to very low sulphur contents by using a burnt lime powder as the desulphurizing agent.

## Lime in Older Processes

In cases where lime has been used for the desulphurization of pig iron, it has generally not been used alone, but mixed with other substances such as fluorspar, to obtain the formation of a molten slag during the process. This method has been tried by Tigerschiöld,<sup>4</sup> who treated the iron with a lime-fluorspar mixture, the stirring of the iron being brought about inductively with low frequency alternating current. Very good results were obtained. A process of this type has also been suggested by R. P. Heuer, U. S. A. The principles of this method, which has been tested in Great Britain by Newell, Langner, and Parsons,<sup>5</sup> are that a mixture of lime and fluorspar is added to the hot metal in the ladle, while a powerful stream of nitrogen gas is blown into the bath to produce the required intermixing. The results of the tests were unsatisfactory, however. A similar process has been developed at The Steel Co. of Canada, according to a statement by H. M. Griffith.<sup>6</sup> Here the tests were carried out in a carbon-lined ladle provided with carbon tuyeres in the side wall for blowing nitrogen into the bath. The addition consisted of about 20 lb of a mixture of burnt lime and fluorspar per ton of pig iron. Good results appear to have been achieved. The sulphur content of the pig iron is stated to have been reduced from 0.025 to 0.050 pct down to 0.006 pct.

Various methods of desulphurizing pig iron have

been tried using lime powder without fluxing material for fusing. Eichholz and Behrendt<sup>7</sup> have experimented with blowing a powdered lime-coke mixture with air into the ladle. Their results were, however, not conclusive and the experiments do not appear to have been continued. Similar experiments have been carried out at Domnarfvet, using nitrogen instead of air in order to avoid oxidation. But these attempts were not particularly successful. It appears to be difficult to achieve the required agitation by this means. The strong cooling effect of the gas on the iron is also a serious drawback.

A method in many respects similar to that tried at Domnarfvet was tried by Eulenberg and Krus at the end of the 1930's. Here again desulphurization was carried out with lime alone, brought into contact with the molten iron in a rotary furnace. The temperature was kept at the required level, 1400° to 1500°C, by the introduction of a pulverized coal burner in one end of the furnace. The speed of rotating was not given. A paper by Bading and Krus<sup>8</sup> states that, in one of the first experiments, the sulphur content in 56 tons of pig iron was brought down from 0.186 to 0.035 pct in 117 min, but that a considerable shortening of the time would be possible. According to later reports by Eichholz and Behrendt,<sup>7</sup> it should be possible by this process to achieve a desulphurization speed of 0.35 pct S per hr for a consumption of 6 to 10 pct limestone and 2 to 3 pct coke, as fuel exclusively. The final sulphur content is, however, not stated.

## Domnarfvet Method

After a number of different procedures had been investigated, the tests at Domnarfvet were directed to desulphurization with lime in a rotary furnace. Before going into the practical details of the method, the theoretical aspects will be discussed briefly.

If the pig iron does not contain alloying elements other than carbon, the reaction can be expressed most simply by the usual equation:

That this reaction can be carried through to a very complete desulphurization of pig iron has been shown by Oelsen<sup>9</sup> in a discussion in connection with the Eulenberg and Krus' method. He mentions two laboratory tests, in one of which the sulphur content in the pig iron at 1400°C was reduced from 0.540 to 0.006 pct after treating with 3.35 pct lime. The pig iron had a low manganese content, but other analysis is not given.

Mention also should be made of the recently published investigations by Fischer and Cohnen<sup>10</sup> dealing with the influence of the carbon content of the iron on desulphurization with lime, although in this case fluorspar was added also. The tests show that efficient desulphurization is possible with lime in the steel bath, provided that the carbon content is sufficiently high. The temperature employed in these tests was considerably higher (1620°) than that normal for treatment of pig iron. The author concludes that the product  $\text{S}\% \times \text{C}\% = 0.011$  at the temperature in question.

B. KALLING, Member AIME, C. DANIELSSON, and O. DRAGGE are associated with the Research Department, Stora Kopparbergs Bergslags Aktiebolag, Domnarfvet, Sweden.

Discussion on this paper, TP 3109C, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, Feb. 27, 1951. St. Louis Meeting, February 1951.

In practice the conditions are complicated by the fact that the pig iron to be desulphurized is very seldom free of silicon. In a pig iron containing silicon above a certain level, the carbon is replaced by silicon as a reducing agent, and the reaction equation may be written:

The silica reacts with the lime present to form a silicate, presumably  $\text{Ca}_2\text{SiO}_4$ , in the main, when there is an excess of lime. The reaction equation will then be:

The formation of silicate here implies that a large part of the lime is bound to the silica, so that the consumption of lime may be much higher in this case than that with silicon-free iron.

How far reaction 3 can be carried, when desulphurizing to a certain sulphur content in the pig iron, is difficult to estimate reliably. A knowledge is required, for instance, of the intersolubility of

Fig. 1—Diagram of furnace showing layout and dimensions.

the different components. Their solubility is probably very limited, so the reaction should be nearly complete even in desulphurizing to a low sulphur content in the pig iron. On the assumption that transformation takes place completely according to eq 3 and that 0.1 pct S is eliminated, the following data are obtained, whatever the sulphur content in the pig iron during treatment: lime consumption, 0.35 pct of the weight of pig iron; oxidation of silicon, 0.05 pct; S and  $\text{SiO}_2$  content of lime product, 20 and 19 pct, respectively.

Some of the test results presented in the following indicate that while the theoretical consumption of lime is roughly that stated above, in practice certain cooperative factors make it necessary to calculate with a considerably higher consumption of lime.

It should be pointed out that reduction with carbon, as above, is endothermic, while silicon reduction is exothermic. The equilibrium of the carbon reaction should therefore be displaced towards lower sulphur contents at a higher temperature, while the opposite applies to reduction with silicon. But since equilibrium for an excess of lime corresponds in both cases to an extremely low sulphur content in the iron, the temperature has no great influence on the reaction. Nor does the temperature appear particularly to affect the rate of reaction within the normal temperature range applying here. The evolution of heat in the silicon reaction is valuable, as the temperature loss in the treatment of the hot metal is thus counteracted to a large extent.

Fig. 2—Furnace as electrodes are being withdrawn.

The silicon content required within this temperature range for the reducing effect of the silicon to exceed that of the carbon, is certainly very low. Our experiments indicate that the reducing action of silicon is as great as that of saturated carbon at a silicon content of about 0.05 pct at  $1300^\circ\text{C}$ .

A matter of prime importance to the result of the process has proved to be that unnecessary oxidation of silicon should be avoided as far as possible. The silica formed opposes the reaction primarily by binding the lime as silicate, but also to a large extent by the silicate adhering to unused grains of lime and thus preventing the latter from intimate contact with the pig iron. The process should therefore take place under strongly reducing conditions. All oxidizing gases should be eliminated from the furnace during treatment. Therefore, the furnace should not be heated with combustion gases even if they are "reducing," i.e., contain unburnt carbon monoxide. As previously stated, even pure carbon monoxide has a strong oxidizing action on silicon in normal contents in the pig iron. The best result should be achieved then if the process is carried out in a closed furnace. Oxygen-free gases, hydrogen, and hydrocarbons, may nevertheless be supplied, which can be of advantage, as the presence of hydrogen should increase the reaction speed. But even when every possible step is taken to prevent external oxidizing gases from entering the furnace during the process, it is difficult to avoid some oxidation of silicon taking place apart from that occurring by the desulphurization reaction.

The lime must be in a very finely pulverized form if a sufficiently large contact surface is to be obtained with the hot metal. The tendency of fine grained lime to form balls must, however, be avoided. For this reason, the temperature of the hot metal must not be kept too high. A safety measure which is generally found desirable, but perhaps not always necessary, is to mix in a certain quantity of fine grained coke dust in the lime to counteract the tendency to stick.

If a rapid reaction is desired, an extremely intensive agitation of lime and hot metal is imperative. A short time of treatment is important not only for the saving in time, but also for the avoidance of an unnecessary temperature loss during the process, which, as stated above, should preferably be carried out without external heating. It has been found necessary to increase the speed of rotation of the furnace to a rate far above that employed with other rotary furnaces for metallurgical use. In this way the time of reaction can be lowered to only a few minutes.

### Results

The first tests with this method were started at Domnarfvet in 1947. They were made in a semiscale, cylindrical rotary furnace with a capacity of about 3 tons. Laboratory experiments were made later to study in greater detail the factors affecting the reactions and the states of equilibrium. This work has, however, not advanced so far that definitive results can be given. During the first half of 1950 operations were started in a plant for commercial use of the method at Surahammars Bruks AB, Surahammar, Sweden. The maximum capacity of the furnaces is about 18 tons. The results obtained from this plant are reported by S. Fornander.<sup>11</sup> The present paper will deal only with the results obtained from tests in the 3-ton furnace at Domnarfvet.

From Fig. 1, which shows the dimensions of the furnace, it can be seen that electrical heating was employed with graphite electrodes introduced through central openings in the two ends. Fig. 2 shows the furnace at a moment when the electrodes

are just being withdrawn, and Fig. 3, during the charging of the pig iron. The tapping of the hot metal and lime charge was made through the visible tap hole in the center of the furnace mantle.

In all experiments the furnace was lined with ordinary fire clay. Desulphurization can be carried through without any formation of balls or lime attack on the furnace lining, as long as the temperature of the pig iron does not exceed about 1350° to 1400°C. A more favorable result may be obtainable through the use of a basic furnace lining such as magnesite or tar-dolomite, or, perhaps even better, a carbon lining. Fire clay, however, has given such satisfactory results that there was no reason to

change to another material, and in any case it appears to be the most economical.

In most experiments the pig iron was first introduced into the furnace, after which a quantity of finely ground, burnt lime in suitable proportion to the pig iron was shovelled on to the surface of the bath, usually mixed with a varying quantity of coke powder. The screen analysis of the lime used is recorded in Table I. The lime charge contained a not inconsiderable amount of CO<sub>2</sub> and H<sub>2</sub>O, which caused a strong development of gas at the beginning of the treatment. After the gas evolution had ceased, the furnace was kept tightly shut. The rate of rotation was in most cases 40 rpm, which was the maximum for the furnace.

In Figs. 4 to 13 the course of desulphurization in a number of tests is shown, as is the change in the silicon content of the hot metal and the temperature loss during each treatment. The temperature of the

furnace when the pig iron was introduced was normally about 1100°C.

Table II gives the analysis of the "end lime" obtained during treatment for the majority of heats. Prior to analysis, the major part of the metallic iron had been separated magnetically. The analysis applies to material having passed through a 65 mesh screen. Much of the product is admittedly coarser, but it was considered important to form a clear picture of how far the reaction could be taken with the finest material. The sulphur content has proved slightly higher in the analyses recorded than in an average sample of the end lime.

The silica content of the end lime does not originate only from the silicon oxidized in reaction 3. Some is obtained from silica in the lime and coke dust, and a varying quantity also from the lining. Generally a certain quantity of silica has been formed through the presence in the furnace of undesirable oxidizing substances, such as iron oxides and sulphates formed through oxidation of residues, in the furnace after tapping the previous charge, carbon dioxide and water vapor from the lime charge, etc. In Table III are recorded the proportions of the different sources of silica in the charges examined.

An attempt has been made to determine the "lime yield" in the different heats on the basis of the analyses, by which is meant the theoretical amount of lime required for the completion of reaction 3

\* At continuous operation, the SiO<sub>2</sub> from the lining is expected to decrease to negligible values.

† The furnace is quite clean at the start of the heat.

‡ The main part of the unwanted SiO<sub>2</sub> content seems to originate from oxidation of products remaining in the furnace from the preceding heat.

§ Heats with both Si and C reduction during the desulphurization.

in proportion to the total quantity actually used. The somewhat doubtful assumption has thus been made that all silica is bound to lime in the form of Ca<sub>2</sub>SiO<sub>4</sub>, and that Al<sub>2</sub>O<sub>3</sub> and the insignificant MnO content need not be taken into consideration. The calculated lime yield therefore will probably be too high in some cases, which is partly shown by the fact that the free amount of CaO has been negative in one case (KR 41). Thus, all silica is not bound as Ca<sub>2</sub>SiO<sub>4</sub>, but is also in the form of other more acid silicates. The result of the calculations is given in Table IV.

The coke added has, like the lime, been finely pulverized. The addition of coke generally has been about half that of lime. A large part of the coke, however, has been used up through dissolving of the carbon in the pig iron, which was not previously

fully saturated with carbon. This is seen by the comparatively low carbon content in the end-lime analyses. In other cases, where the pig iron is high in silicon, there has been a considerable separation of graphite during the process, which means that a smaller amount of coke is required. How much coke is needed under different conditions has not been fully worked out, but that a certain, even if small, addition is desirable has been clearly shown from the experiments.

Figs. 4 to 6 show some normal heats. In the case of heat KR-8 a pig iron fairly high in silicon, but with low phosphorus content, has been treated, while the other two diagrams show the desulphurization of a basic bessemer pig iron of normal analysis. As will be seen, the desulphurization is very rapid if the amount of lime is sufficient, and about equally so whether the pig iron is high or low in silicon. The lesser amount of lime in experiment KR-36 (Fig. 6) caused a slower and less complete reaction. The experiment shows, however, that a considerable desulphurization can be obtained with the addition of only about 1 pct lime. The yield of lime, 58 pct according to Table IV, in this case is very satisfactory.

The silicon content in the pig iron sinks, in all cases, by about 0.05 pct, which shows that the losses through "foreign" oxidation have been negligible.

The temperature drop during the process is about 50°C (rather more in heat KR-36), which is satisfactory considering the small size of the furnace. It can be assumed that heating 1 pct dry carbon dioxide-free lime to the reaction temperature will cool the hot metal by about 15°. The corresponding figure for coke dust is about 25°. The heat of reaction in the presence of silicon, on the other hand, corresponds to an increase in the temperature of the hot metal by about 10° for oxidation of 0.05 pct Si. The resulting temperature drop in desulphurization of a pig iron containing about 0.1 pct S with 1.5 pct lime and 0.5 pct coke is calculated from these figures

to be about 25°. About 10° to 20° should always be added to cover radiation losses, etc.

Heats KR-41 and KR-42 in Fig. 7 are examples of how far desulphurization can be brought in one operation commencing with pig iron with a sulphur content of between 0.3 and 0.4 pct. In charge KR-42 the sulphur content has been brought down from 0.31 to under 0.003 pct when using 3.8 pct lime, i.e., an elimination of 99 pct. The lime yield is high notwithstanding, 58 pct according to the calculations. In heat KR-41, where the addition of lime was only half as great, 1.9 pct, the sulphur content sank only to 0.072 pct in 20 min, but at this time was still sinking. The yield of lime here, as already stated, was over 100 pct, according to the method of calculation used, but still as high as 78 pct if all silica is assumed to be in the form of  $\text{CaSiO}_3$  instead of  $\text{Ca}_2\text{SiO}_4$ . A sulphur content in the end lime of 15.6 pct, as in this case, with a simultaneous silica con-

tent of 17 pct, is an unusually high figure, which would hardly be attained in practice if the sulphur content is at the same time to be lowered to values below 0.025 pct.

At low silicon contents, the carbon as reducing agent also takes part in the reaction. At high sulphur contents an appreciable evolution of carbon monoxide can be noticed even at quite high silicon contents, such as 0.3 to 0.4 pct. This was the case, for instance, with the last described heats, KR-41 and KR-42. With lower ingoing sulphur contents, however, the silicon content must be under 0.05 pct, if the carbon is to take part in the reaction to any appreciable extent.

Figs. 8 to 10 show three heats, in which the carbon has, for the most part, taken over the role of silicon as reducing agent. It might be possible to deduce from these results that equilibrium between saturated carbon and silicon is about 0.05 pct Si at 1300°, and at 1200° about 0.02 pct.

In heat KR-40 (Fig. 10) the manganese content of the pig iron was 1.2 pct. This was maintained practically unchanged throughout the heat, which is partly shown by the low manganese content in the end lime. This reveals that the manganese content of the pig iron did not appreciably promote desulphurization, either as a reducing agent, or on account of its sulphur binding capacity.

Due to the rapid rotation of the furnace during the process, small drops of iron are formed that are mixed up in the lime charge and remain in the end lime. It is therefore advisable to allow the lime powder to pass a magnetic, dry separator after the process, by which the main part of the iron can be recovered. The grains can either be returned to the process or put back in the blast furnace, if other uses are not possible. Certain means have been found of counteracting the generation of these grains in the end lime. An addition of soda to the lime has a favorable effect in this respect. If the addition is not too great, at most about 10 pct of the amount of lime, the soda does not appear to exert any great influence on the sticking tendency of the lime charge.

In Fig. 11 the result of an experiment with an addition of soda is recorded. The rate of reaction has

Fig. 12—Heat KR30, KR31, KR32, KR33, and KR34.

Fig. 13—Heat KR16 and KR18.

KR16 (solid line) — Hot metal, 2370 kg; C, 3.2 pct; 20 rpm. Lime powder, 38 kg; Mn, 0.5 pct. Coke powder, 19 kg; Si, 0.32 to 0.30 pct; P, 1.5 pct.  
KR18 (broken line) — Hot metal, 2500 kg; C, 2.9 pct; 40 rpm. Lime powder, 40 kg; Mn, 0.5 pct. Coke powder, 20 kg; Si, 0.57 to 0.54 pct; P, 1.8 pct.

been very slightly higher than normal, which can be ascribed to a certain catalytic influence from the soda addition. As will be seen from Table II, the sodium content in the lime charge has, however, been practically completely volatilized.

It is of course desirable from many points of view that the necessary quantity of lime be as low as possible. Even if the saving in lime is in itself of no great economic significance, a lower addition of lime has, among other things, the advantage of a smaller temperature drop in the hot metal. It seems that the amount of lime required for desulphurization of a pig iron from, for instance, 0.100 to 0.010 pct need not be expected to exceed 1 pct of the weight of the pig iron. When so small an amount of lime is used, however, the lime charge will form a thin and therefore comparatively stationary layer on the iron bath during the rotation, whereby the mixing effect may deteriorate. In order to be able to maintain a sufficiently high layer of lime in the furnace, without increasing the percentage of lime, it can be arranged so that the lime is retained in the furnace, when the hot metal is discharged, and re-employed for one or several subsequent operations. The result of an experiment along these lines is found in Fig. 12 and Table V.

Altogether 12.5 tons of pig iron was introduced in five stages, i.e., about 2.5 tons at a time. The whole amount of lime, 240 kg, was introduced at the beginning, thus corresponding to practically 10 pct of the lime present in the furnace at each treatment. Apart from the first operation, which was carried out at much too low a temperature due to the cooling effect of the large quantity of lime, in all cases the desulphurization went down to low contents very rapidly. Particularly remarkable is the rapid and complete sulphur removal even in the last experiment, although the lime in this case must, from the beginning of the treatment, have had a sulphur content of about 5 pct.

The method here described of sulphur removal in stages may be found suitable especially when very large quantities of hot metal are to be handled. Admittedly there does not appear to be any technical objection to building large furnaces, e.g., up to 100 tons capacity, but it may be preferable to employ a smaller furnace and repeat treatment several times, thus putting the lime to better use. The total treatment time need not be much longer on that account, as each part of the operation would proceed more rapidly.

As the tests have shown that desulphurization can be effected in only a few minutes, it is certainly also possible to arrange for continuous treatment by passing the hot metal at a suitable speed through a long rotating drum, in which the lime has either been placed in advance or is fed simultaneously. This procedure has been tested on small scale with promising results. Possibly an even better result can be achieved, if the lime is made to pass in counter-current to the iron by means of suitable sluice arrangements. To judge from the test results in Fig. 12, however, there does not appear to be much to be gained from employing the countercurrent principle.

The rate of rotation of the furnace can have a decisive influence on the result. In most tests 40 rpm has been used, as previously mentioned, and at this rate satisfactory results were always obtained. A few tests were made at 20 rpm, but desulphurization was not nearly so efficient.

Fig. 13 shows two heats, one at 40 rpm and the other at 20 rpm. Otherwise the treatment of the two heats was identical. At the lower rate, desulphurization proceeded far too slowly, but when the speed was increased to 40 rpm at the end of treatment, a more rapid desulphurization immediately occurred. Which rate is most suitable in different cases is hard to determine in advance, but there have been no practical difficulties whatever at the rotation speeds described. Mixing of course can be performed more efficiently by giving the furnace a form which deviates from the circular. Model experiments, for instance, have shown that the agitation effect can be greatly increased by making the furnace section slightly oval.

Finally it may be mentioned that a number of tests have been made with the addition of certain other substances to the lime charge in an attempt to improve the result still further. The addition of aluminum and calcium carbide has been tried in certain tests to increase the reducing effect. The additions resulted in a reduction of silicon to the pig iron from the furnace lining, but the desulphurization efficiency deteriorated, principally because of an increased tendency of the lime charge to form balls. Dolomite can be used as a substitute for lime, but lime is to be preferred.

The end lime obtained always has a high sulphur content, as the analyses show. The silica content has also been comparatively high in several of the tests, but if the attempt is made to avoid all unnecessary silicon oxidation and other introduction of silica, it can be kept at a low level in relation to the  $\text{CaO} + \text{CaS}$  content. The end lime should therefore be a valuable addition for sintering of iron ore, where this takes place. Most of the sulphur content then escapes in gas form.

### Summary

The method described has been carried out in a 3-ton rotating furnace at Domnarfvet Iron and Steel Works. It has the following characteristic features.

The molten iron is brought into intimate contact with powdered burnt lime by treatment in a rapidly rotating furnace.

The treatment has to take place under strongly reducing conditions, which can be made in a simple way by keeping the furnace tightly closed during the process.

The lime must be maintained in the fine powdered form during the whole treatment, which is made possible both by avoiding a temperature in excess of  $1350^{\circ}$  to  $1400^{\circ}\text{C}$  and by the addition of a suitable amount of coke powder to the lime.

By carrying out the process in this way it has been found possible to desulphurize hot metal down to very low sulphur contents in a few minutes even from relatively high starting values, and with a high lime yield.

Owing to the short time of treatment and the small lime addition necessary, the drop of temperature during the process has been very small, with the consequence that external heat supply and its associated disadvantages have been avoided.

The rotation speed normally has been the maximum of the furnace, 40 rpm. Lower speeds have also been tried, but with unsatisfactory results. No inconveniences with the high speed have been encountered.

The advantages of the method can thus be summarized as follows:

1—A very rapid and complete desulphurization can be obtained. The sulphur content can in one operation be brought down to very low values even with high starting content in the iron and with high lime yield.

2—The desulphurizing material is cheap and can be obtained everywhere. After the treatment it may be used for other purposes.

3—No formation of molten slag is taking place, with the result that attack on the lining of furnace and ladle is avoided. The furnace is of a simple construction and can advantageously be lined with ordinary fire clay.

4—The iron during the tapping can be separated easily from the lime.

5—No dangerous smoke is formed during the process.

The first plant for commercial production is in operation at Surahammar Iron and Steel Works, Surahammar, Sweden.

# Kalling-Domnarfvet Process at Surahammar Works

by Sven Fornander

An account is given of the way in which a new process for desulphurization of hot metal is carried out at a Swedish blast-furnace plant. In the process powdered burnt lime is used as a desulphurizing agent in a rotary furnace. Results are given.

IN a paper by Kalling et al.\* the fundamentals of a new process for desulphurization of hot metal using powdered burnt lime as a desulphurizing agent were outlined. The purpose of the present paper is to give a brief account of the way in which this process is being carried out in practice by Surahammars Bruks AB, Sweden, and of the results obtained.

The hot metal from the blast furnace is tapped into a ladle of 15 tons capacity and transferred to a rotary furnace, a simplified drawing of which is given in Fig. 1. The rotary furnace has a total length of about 160 in. and an outside diameter of the rings of about 130 in. The furnace is in a horizontal position, with its rings placed on four rollers, and can be rotated by a driving mechanism at various speeds of up to 34 rpm. The rotary furnace and its driving mechanism were designed and constructed at Surahammar.

The hot metal is charged into the rotary furnace through the opening to the left in Fig. 1. See Fig. 2. An addition is then made to the furnace consisting of finely ground burnt lime amounting to 2 pct of the weight of the hot metal as well as 0.5 pct of coke breeze. After the additions are made, the furnace is sealed to the atmosphere by means of two lids and set in rotary motion at a rate of 34 rpm. The sulphur in the hot metal is rapidly absorbed by the lime added, the time of treatment needed is normally 30 min. The process is then stopped, the lid is removed, and the furnace is lifted up by a crane and used as a tilting ladle for pouring the metal into the pig-iron molds, Fig. 3.

## Process Metallurgy

The hot metal charged into the rotary furnace has a composition which usually lies within the following limits: C, 3.70 to 4.10 pct; Si, 0.80 to 1.80; Mn, 0.40 to 0.80; P, 0.025 to 0.030; and S, 0.060 to 0.200. Figs. 4 and 5 give examples of the changes in hot metal composition taking place during the treatment in the rotary furnace. As will be seen from

S. FORNANDER, Member AIME, is Research Manager, Surahammars Bruks Aktiebolag, Surahammar, Sweden.

Discussion on this paper, TP 3110C, may be sent, 2 copies, to AIME by Oct. 1, 1951. Manuscript, March 7, 1951. St. Louis Meeting, February 1951.

Fig. 1—Rotary furnace for desulphurization.

the diagrams, the sulphur content of the metal decreases very rapidly during the first 10 min of treatment from about 0.100 to about 0.020 pct S. During the following 20 min, the sulphur content goes down slowly to about 0.005 pct S. The carbon and silicon contents of the metal decrease by about 0.10 pct each during the treatment. The manganese and phosphorus contents remain unchanged. Thus, if the process is started with an iron of the composition given above, the finishing composition of the metal usually lies within the following limits: C, 3.60 to 4.00 pct; Si, 0.70 to 1.70; Mn, 0.40 to 0.80; P, 0.025 to 0.030; and S, 0.002 to 0.020.

The chemical reaction taking place during the process can be written:

\* B. Kalling, C. Danielsson, and O. Dragge: Desulphurization of Pig Iron with Pulverized Lime. This issue, p. 732.

Fig. 2—Charging of the furnace.

Fig. 3—Tapping of the furnace.

The sulphur in the hot metal is absorbed by the burnt lime under formation of calcium sulphide, and the oxygen liberated from the calcium oxide combines with silicon, which is in solution in the iron, forming silica. Thus silicon is the reducing agent in the process. From the reaction formula it is obvious that the process is promoted by reducing conditions. It is quite likely that during the process the silica formed combines with lime in the form of a calcium silicate.

It may probably be said that the process is a unique one in the metallurgy of iron and steel with regard to the fact that a solid phase is reacting with a liquid metal. No liquid slag is formed during the process. After finished treatment of the iron, the "lime" (the reaction product) still is in the form of a fine powder.

The fact that the reaction takes place in the surface of contact between the solid lime and the liquid metal is of practical consequences. In order that the reaction should proceed rapidly, the surface of contact must be large. This is the reason why the lime used is in the form of a powder and also, why

a rotary furnace is required in the process. In the rotary furnace an intimate contact is brought about between the liquid metal and the solid lime. Within each of the two phases an efficient stirring action is produced.

### Factors Affecting Desulphurization

The first trials on a commercial scale with the process described above were made in May 1950 at the blast-furnace plant of Surahammars Bruks AB. In the first trials the sulphur content of the hot metal treated was not uniform from cast to cast. Since then, however, various measures have been adopted with the result that during the last few months the process has been applied continuously and given uniform results. The following factors have been found to have an influence upon the results obtained.

**Lime Character:** The lime powder used should be as pure as possible, the most harmful impurities being silica, carbon dioxide, and water. Detailed investigations on the influence of the impurities upon the desulphurization have yet not been carried out, but as rule of thumb it can be said that if the silica content of the burnt lime exceeds 5 pct, the sulphur content of the metal treated will be higher than 0.010 pct S. During the last few months of operation, the lime used has been burnt at the plant in a small and simple furnace with blast-furnace gas as a fuel. The burnt lime is stored in an air-tight container before being ground. The screen analysis of the lime powder used is given in Table I.

**Oxidation:** If good desulphurization is to be obtained, it is of particular importance that the furnace chamber is not exposed to oxidizing conditions either during the desulphurizing treatment of the metal or during the time elapsing between the treatments. During the first few months of operation, the furnace was heated between the treatments by a gas burner, which was inserted through a central opening in one end of the furnace. During this period of time, the desulphurization was incomplete and the results varied considerably. Prob-

Table I. Screen Analysis of Lime Powder

| Sieve Opening, mm | Percent |
|-------------------|---------|
| Over 1.5          | 4.0     |
| 1.5-1.0           | 2.6     |
| 1.0-0.6           | 5.4     |
| 0.6-0.3           | 5.8     |
| 0.3-0.2           | 14.3    |
| 0.2-0.1           | 19.1    |
| 0.1-0.06          | 17.4    |
| Under 0.06        | 31.4    |

ably this was due to the fact that small amounts of iron sticking to the furnace wall were oxidized by the combustion gases from the burner, the oxides formed decreasing the desulphurizing effect of the lime. However, when the furnace was sealed to the atmosphere both during the treatments and the time elapsing between them, the method gave fully satisfactory results.

If oxidizing conditions prevail in the furnace during the treatment, the lime powder forms balls when the furnace is in rotary motion. In unfavorable cases, these balls can be up to 8 in. diam. Balls will form also, if blast-furnace slag enters the furnace. The occurrence of balls is an indication of incomplete desulphurization. Difficulties of this kind have not appeared during the last few months of operation.

**Furnace Lining:** The furnace lining consists of an inside 6 in. course of ordinary fireclay bricks and two outside courses of insulating bricks having a thickness of 2½ in. each.

Table II. Results of Desulphurization of 300 Casts

| Before Treatment |              | After Treatment |              |
|------------------|--------------|-----------------|--------------|
| S, Pct           | No. of Heats | S, Pct          | No. of Heats |
| 0.020-0.050      | 51           | 0.002-0.010     | 216          |
| 0.051-0.100      | 127          | 0.011-0.020     | 60           |
| 0.101-0.150      | 87           | 0.021-0.030     | 21           |

| 0.201 and over   | 10           |                 |              |
| Average 0.095    | 300          | 0.009           | 300          |

After a treatment of a cast in the furnace, the inside wall is covered with a thin adhering layer, consisting of a mixture of lime powder, coke breeze, and solidified iron. The layer grows thicker with every cast treated, and when 50 or 60 casts have been treated, the layer is so thick that the furnace room is insufficient. The layer is removed by heating the furnace wall to a high temperature, about 1400°C, by means of an oil burner. However, the heating must be made with care in order to prevent the fireclay bricks from being damaged.

At present a new rotary furnace is under construction, and this unit will be provided with a basic lining. The unit will be used when the existing one is under relining.

**Hot Metal Temperature:** The temperature of the hot metal was determined at various stages of the process by means of quick-immersion thermocouples. The following figures refer to normal conditions: In blast-furnace runner, 1400°C (2550°F);

| Average  | 11                    | 0.082            | 0.006           | 92.7                   |

Fig. 6—Results of desulphurization of 300 casts.

in ladle when full, 1340°C (2440°F); in rotary furnace before treatment, 1320°C (2400°F); and in rotary furnace after 30 min treatment, 1250°C (2280°F).

Thus the temperature loss during the whole process amounts to about 150°C (270°F). A hot-metal temperature of 1250°C (2280°F) is sufficient for pouring the metal into the molds. However, at Surahammar's blast-furnace plant, the iron is partly used for the manufacture of ingot molds, and for this purpose a temperature of 1250°C is too low. In the near future, the hot metal will be tapped from the blast furnace directly into the rotary furnace. This procedure will probably reduce the temperature loss to 70° or 80°C, and it is intended to use the hot metal treated in the rotary furnace in the ingot mold foundry. Variations in the temperature of the hot metal seem to have no influence upon the desulphurization obtained.

Results Obtained

In order to illustrate the desulphurizing effect that can be expected if the process is used in practice, a collection has been made of the results obtained in the treatment of the last 300 casts from the blast furnace, Table II and Fig. 6.

As will be seen from the table the majority of the casts (249 out of 300) had a sulphur content before treatment of 0.051 pct S or more. The sulphur content in the casts treated was 0.010 pct S or less in 216 cases and 0.020 pct S or less in 276 cases.

The average sulphur content of the iron cast from the blast furnace was 0.095 pct S during the period in question. The average sulphur content of the iron treated in the rotary furnace was 0.009 pct S. This implies that on an average 90.5 pct of the sulphur in the hot metal was removed in the rotary furnace.

Table III shows results of three days' operation. The values confirm that the desulphurizing process described above is an effective one.

Summary

An account is given of the results obtained by Surahammars Bruks AB, Sweden, with a new process for desulphurization of hot metal from a blast furnace. In the process the hot metal is treated with finely ground powder of burnt lime in a rotary furnace. About 90 pct of the sulphur in the metal is removed in the process, which after some months of experience has been found simple and inexpensive in operation.

The author is indebted to Einar Ameén, Managing Director, and Yngve Törneman, Technical Director, of Surahammars Bruks AB, for their kind permission to publish the results presented in this paper.

# A Corrected CO/CO<sub>2</sub> Ratio for Blast Furnaces

by Sid T. Killian

The utilization of the reducing power of blast-furnace gas can be estimated by applying two rectifying calculations to the gas analysis. A resulting corrected CO/CO<sub>2</sub> ratio varies inversely with furnace production. Directions for calculating the corrected CO/CO<sub>2</sub> ratio are given, and a corrected CO/CO<sub>2</sub> ratio is compared with actual furnace production.

THE inadequacy of the normally accepted CO/CO<sub>2</sub> ratio as a measure of blast-furnace performance and furnace efficiency was discussed following the presentation of the paper by H. F. Dobscha.\* In this outstanding example of careful observation on large scale blast-furnace operation, the changes occurring with beneficiated ores were: 1—A net gain in tonnage of 21.2 pct. 2—A decrease in net coke of 15.3 pct. 3—A decrease of 1.9 pct in the CO/CO<sub>2</sub> ratio. In this great change in furnace performance, the CO/CO<sub>2</sub> ratio proved itself worthless.

The discussion of the inadequacy of expressing furnace performance and efficiency by the CO/CO<sub>2</sub> ratio led indirectly to the calculations forming the basis of this paper. At that time Dr. T. L. Joseph said: "We must consider difference in CO<sub>2</sub> from the stone in the two cases when we talk about the ratios

of CO/CO<sub>2</sub>." This statement is used for the second of the two CO/CO<sub>2</sub> ratio corrections forming the basis of this paper.

The research work in attempting to find out why the furnaces could operate so differently with practically the same CO/CO<sub>2</sub> ratio lead not to the answer sought but, after a shift to the gaseous phase in the research work, the proof that the normal CO/CO<sub>2</sub> ratio was outmoded and a new corrected ratio should replace it. To be of any value, any new corrected ratio should express approximate furnace efficiency and give an idea of practical furnace performance to be expected. This the normal CO/CO<sub>2</sub> ratio has failed to do. However, in the absence of anything better, some credence has been attached to the normal CO/CO<sub>2</sub> ratio. As far as the writer can ascertain, the present paper is the first attempt to change or improve the normally accepted index of

furnace efficiency. A corrected CO/CO<sub>2</sub> ratio is proposed as the future criterion of the blast furnace.

### Corrections Necessary

The calculations involved in figuring the corrected CO/CO<sub>2</sub> ratio are performed in two main steps. The first calculation involves placing the gas analysis on a hydrogen-free basis. The second calculation consists of deducting the amount of CO<sub>2</sub> evolved by the flux from the gas analysis.

The first correction is almost mandatory, if the CO/CO<sub>2</sub> ratio is to be continued as a measure of furnace efficiency, inasmuch as it can be figured so easily. The second step however should be adapted to furnace records and must be used carefully to render true service.

When the gas analysis is placed on a hydrogen-free basis, the CO/CO<sub>2</sub> ratio expresses the ratio of the total unused reducing power to the used reducing power with the flux CO<sub>2</sub> included as used reducing power. The normal CO/CO<sub>2</sub> ratio attempted to give a ratio of unused to used reducing power, but the resulting ratio could vary considerably due to the exclusion of the hydrogen content of the gas and the inclusion of the flux CO<sub>2</sub> in the ratio. However when both corrections are made, a close expression of the ratio of unused reducing power to used reducing power in the gaseous phase is obtained. Neither correction should be omitted if any resulting corrected CO/CO<sub>2</sub> ratio is to be used as a representation of furnace efficiency or furnace performance.

### Chemical Principles of the First Correction

*Gas Analysis on a Hydrogen-Free Basis:* The gas-analysis correction of placing the gas analysis on a hydrogen-free basis in no way involves furnace reactions, but merely corrects the gas analysis for a variable which can change the actual gas analysis and the ratio calculated from it.

The equation:

shows how the interaction of the CO<sub>2</sub> and the H<sub>2</sub> with the CO and the H<sub>2</sub>O can change the ratio. As the H<sub>2</sub> increases, the CO<sub>2</sub> is increased at the expense of and in the same amount as the CO is decreased. Similarly, as the H<sub>2</sub> decreases, the CO<sub>2</sub> is decreased in the same amount as the CO is increased. The variable of the hydrogen content of the gas is eliminated by changing the gas analysis so that the reaction goes to completion in the direction that eliminates the hydrogen. The two components of the CO/CO<sub>2</sub> ratio are then left for the calculation. Thus the correction merely involves the subtraction of the percentage of hydrogen in the gas from the percentage of carbon

dioxide in the gas and the simultaneous addition of the percentage of hydrogen in the gas to the percentage of carbon monoxide in the gas. In other words, every 1 pct of H<sub>2</sub> in the gas analysis will drop the CO<sub>2</sub> percentage exactly 1 pct and simultaneously raise the CO percentage exactly 1 pct when the correction is made.

In order to show clearly how the hydrogen content of the gas changes the normal CO/CO<sub>2</sub> ratio, Table I has been calculated. In it all volumes are changed entirely by the reaction:

in steps of 0.50 volumes of each of the reacting gases. All the analyses and CO<sub>2</sub> ratios in Table I are identical when placed on the hydrogen-free basis. All given an identical corrected ratio of 2.683.

### Second Correction

*Gas Analysis with Flux CO<sub>2</sub> Deducted:* While the CO<sub>2</sub> evolved from the stone is an important factor in furnace performance and furnace efficiency, from an overall viewpoint, the calcining of the stone consists of the addition of CO<sub>2</sub> (completely oxidized carbon) to the gaseous phase. The inclusion of this CO<sub>2</sub> tends to give an illusion that a greater oxidation of carbon is taking place than really occurs. In other words, the inclusion of this CO<sub>2</sub> tends to hide the real efficiency.

The second correction of taking the gas analysis on a hydrogen-free basis and deducting the CO<sub>2</sub> evolved from the flux is best accomplished by equating the total carbon input with the total carbon output. The easiest means of computing this carbon balance should be to use 24 hr as the basis with no calculations involving the wind blown. The blowing media used vary widely in efficiency and quite often the wind ordered differs markedly from the actual wind delivered. Thus complex stoichiometric calculations are avoided and practically all calculations can be made from furnace records.

*Carbon Balance:* The carbon input normally includes: 1—net coke carbon to furnace excluding fractions not charged, 2—carbon in stone, and 3—carbon in scrap. The carbon output normally includes: 1—CO in gas, 2—CO<sub>2</sub> in gas, 3—carbon in total amount of pig iron produced, 4—carbon in flue dust and sludge, 5—coke messes, 6—rolls and slips, 7—carbon in the gas as coke particles and as stone particles, and 8—hydrocarbons in the gas.

All the items should be observed and calculated before assuming them to be negligible. For a complete carbon balance, every item should be checked.

*Illustration of Calculation:* The corrected CO/CO<sub>2</sub> ratio is illustrated in the calculation of a furnace using 1.00 fuel (80 pct net carbon) with 300 lb of

Table II. Calculation of Corrected CO/CO<sub>2</sub> Ratio

|                                                                 |       |
|-----------------------------------------------------------------|-------|
| <b>Input</b>                                                    |       |
| Coke, net lb carbon per ton pig.....                            | 1600. |
| Stone, net lb carbon per ton pig.....                           | 100.  |
| Input, net lb carbon per ton pig.....                           | 1700. |
| <b>Output</b>                                                   |       |
| Pig iron, net lb carbon (4.2 pct).....                          | 84.   |
| Flue dust, net lb carbon.....                                   | 30.   |
| Gas, net lb carbon by difference.....                           | 1586. |
| Output, net lb carbon per ton pig.....                          | 1700. |
| Fraction carbon in gas from flux = 100/1586 = 0.0631            |       |
| In gas analysis from flux = (30.10 + 11.22) × 0.0631 = 2.61 pct |       |
| In gas analysis not from flux = 11.22 — 2.61 = 8.61 pct         |       |
| In gas from furnace reactions = 8.61 pct                        |       |

Table III. Blast Furnace Performance

| Ores Used                             | Normal | Beneficiated | Difference, Pct |
|---------------------------------------|--------|--------------|-----------------|
| Iron production, net tons per day     | 1324   | 1605         | +21.2           |
| Coke, net lb per ton                  | 1782   | 1510         | -15.3           |
| Flue dust and sludge, lb per ton      | 284    | 227          | -20.1           |

| Analysis of top gases, pct            |        |              |                 |
| CO                                    | 26.57  | 26.17        |                 |
| CO <sub>2</sub>                       | 12.33  | 12.40        |                 |
| H <sub>2</sub>                        | 2.30   | 1.60         |                 |
| CH <sub>4</sub>                       | 0.13   | 0.13         |                 |
| N <sub>2</sub>                        | 58.67  | 59.70        |                 |
| Ratio CO/CO <sub>2</sub>              | 2.15   | 2.11         |                 |

flue dust (10 pct carbon). Carbon in the flux is taken at 100 lb per ton of pig iron. The gas analysis equating the various CO/CO<sub>2</sub> ratios to a hydrogen-free basis is used for this calculation, Table II.

Thus with the gas analysis illustrated and containing 2.00 pct hydrogen, the normal CO/CO<sub>2</sub> ratio is 2.115. The CO/CO<sub>2</sub> ratio on a hydrogen-free basis is 2.683. The corrected CO/CO<sub>2</sub> ratio on a hydrogen-free basis with the correction for the CO<sub>2</sub> evolved from the flux is 3.496.

#### Comparison of Corrected CO/CO<sub>2</sub> Ratio with Furnace Performance

The method involved in calculating the corrected CO/CO<sub>2</sub> ratio from the Dobscha-United States Steel furnaces differs markedly from the preceding calculations, which are given as the method to be used normally. In the following calculations, the corrected CO/CO<sub>2</sub> ratio is calculated from the carbon distribution in the gas, since complete figures for calculating by the carbon-balance method were not included in the paper. Then the old ratio and the corrected CO/CO<sub>2</sub> ratio are compared with the furnace production. In other words, the old and the corrected CO/CO<sub>2</sub> ratios are being checked against the performance of the Dobscha-United States Steel furnaces.

For the benefit of any who have not read Dobscha's paper,\* the following is taken directly from it: "A program was carried out involving two modern identical blast furnaces with a hearth diameter of

|                                                                 | Normal Ores      | Beneficiated Ores |
|-----------------------------------------------------------------|------------------|-------------------|
| Carbon in CO, lb                                                | 1024             | 838               |
| Carbon in total CO <sub>2</sub> , lb                            | 475              | 397               |
| Carbon in flux CO <sub>2</sub> , lb                             | 113              | 76                |
| Fraction of total carbon in the gas evolved from the flux       | 113/(1024 + 475) | 76/(838 + 397)    |
| Percentage of the total carbon in the gas evolved from the flux | 7.54             | 6.15              |

Table V. Percentage CO<sub>2</sub> from Flux

| Gas Analysis, Hydrogen Free      | Normal Ores | Beneficiated Ores |
|----------------------------------|-------------|-------------------|
| CO in gas, pct                   | 28.87       | 27.76             |
| CO <sub>2</sub> in gas, pct      | +10.03      | +10.80            |
| Total CO + CO <sub>2</sub> , pct | 38.90       | 38.56             |
|                                  | × 0.0754    | × 0.0615          |
| CO <sub>2</sub> from flux, pct   | 2.93        | 2.37              |

27 ft 6 in. A mixture of beneficiated ores was charged on one furnace for a continuous period of one month and normal ores charged on the other furnace. During an interim period of one month, the burdens were reversed and the test was continued for a two-month period. Coke, flux, and miscellaneous burdening materials were of the same quality on both furnaces; the quantities of the latter being identical except for deviations dictated by operating practice." Table III is taken from p. 55 of the 1948 *Proceedings of the Blast Furnace, Coke Oven and Raw Materials Committee, AIME*.

#### Gas Ratio Calculated to a Hydrogen-Free Basis

The gas ratio calculated to a hydrogen-free basis follows:

| Normal Ores  | Beneficiated Ores |
|--------------|-------------------|
| 26.57 + 2.30 | 26.17 + 1.60      |
| 12.33 - 2.30 | 12.40 - 1.60      |
| 28.87        | 27.76             |
| 10.03        | 10.80             |
| 2.878        | 2.562             |

#### Corrections for Flux CO<sub>2</sub> in Gas Analysis

The second correction in calculating the corrected CO/CO<sub>2</sub> ratio is to deduct the CO<sub>2</sub> evolved by the flux from the total CO<sub>2</sub> in the gas analysis on a hydrogen-free basis. In this case it is performed in three steps. 1—The fraction or percentage of total gas carbon which comes from the flux carbonate is calculated. 2—This fraction or percentage then is expressed as percentage CO<sub>2</sub> in the gas analysis. 3—The percentage CO<sub>2</sub> from the flux is subtracted from the CO<sub>2</sub> in the gas on a hydrogen-free basis. The corrected CO/CO<sub>2</sub> ratio can then be calculated.

*Percentage of Total Gas Carbon from Flux Carbonates:* The first step in tying in the CO<sub>2</sub> from the flux with the CO<sub>2</sub> in the gas analysis is to calculate the percentage of the carbon in the gas which comes from the flux. The figures for that calculation follow.

The carbon distribution in the top gases in Dobscha's furnaces is given in Table IV.

*Gas Analysis Percentage of CO<sub>2</sub> from Flux Carbonate:* The second step in tying in the CO<sub>2</sub> from the flux with the CO<sub>2</sub> in the gas analysis is to find the percentage of CO<sub>2</sub> which came from the flux expressed in gas analysis percentage. This calculation

Table VI. Correction of Gas Analysis for CO<sub>2</sub> from Flux

| Gas Analysis, Hydrogen Free                 | Normal Ores | Beneficiated Ores |
|---------------------------------------------|-------------|-------------------|
| CO <sub>2</sub> in gas, pct                 | 10.03       | 10.80             |
| CO <sub>2</sub> from flux, pct              | -2.93       | -2.37             |
| CO <sub>2</sub> from furnace reactions, pct | 7.10        | 8.43              |

Table VII. CO/CO<sub>2</sub> Ratio vs. Production

|                                                                                 | Normal Ores | Beneficiated Ores | Comparative Ratio |
|---------------------------------------------------------------------------------|-------------|-------------------|-------------------|
| Production, tons pig iron                                                       | 1324        | 1605              | 0.8249            |
| CO/CO <sub>2</sub> ratio, regular gas analysis                                  | 2.1549      | 2.1105            | 1.021             |
| CO/CO <sub>2</sub> ratio, corrected for H <sub>2</sub>                          | 2.878       | 2.562             | 1.123             |
| CO/CO <sub>2</sub> ratio, corrected for H <sub>2</sub> and flux CO <sub>2</sub> | 4.066       | 3.293             | 1.235             |
| Inverse ratio of pig iron production                                            |             |                   | 1.212             |

is given in Table V. These figures show the direct amount in gas analysis percentages of  $\text{CO}_2$  evolved from the flux. In other words, these calculated percentages of  $\text{CO}_2$  are to be deducted from the total percentage of  $\text{CO}_2$  on a hydrogen-free basis.

*Gas Analysis Correction for  $\text{CO}_2$  Evolved from Flux:* The calculations correcting the gas analysis on a hydrogen-free basis for the  $\text{CO}_2$  evolved from the flux is given in Table VI.

The corrected  $\text{CO}/\text{CO}_2$  ratio then is:

|       |       |
|-------|-------|
| 28.87 | 27.76 |
| 7.10  | 8.43  |
| 4.066 | 3.293 |

The above figures show the corrected  $\text{CO}/\text{CO}_2$  ratio calculated on a hydrogen-free basis with the correction for the  $\text{CO}_2$  evolved from the flux.

The ratios 1.235 and 1.212 in Table VII show how closely the ratio of the corrected  $\text{CO}/\text{CO}_2$  ratios compares with the ratio of iron production in an inverse manner. Mathematically:

$$\text{Production} \times \text{Corrected Ratio} = \text{A Constant}$$

As shown in Table VIII, the product of the corrected  $\text{CO}/\text{CO}_2$  ratio and the iron production differ by approximately 2 pct when the normal and beneficiated ores are compared. In other words, the product of the corrected  $\text{CO}/\text{CO}_2$  ratio and the iron production should approximate a constant when similar furnaces are compared or when conditions are changed on the same furnace.

This constant might be one of the benefits of the corrected  $\text{CO}/\text{CO}_2$  ratio as a tool of production. However, the constant might not be a straight-line function of the inverse production and checking should be done before it can be accepted as such. For normal changes on one furnace, the variation from a straight line would be negligible. At this time, the constant is used only to illustrate the close tie-in of the corrected  $\text{CO}/\text{CO}_2$  ratio with the corresponding furnace production.

### Summary and Conclusions

1—A corrected  $\text{CO}/\text{CO}_2$  ratio is proposed as an index of blast-furnace performance. It is the  $\text{CO}/\text{CO}_2$  ratio of the blast-furnace gas on a hydrogen-free basis with the flux  $\text{CO}_2$  deducted from the gas analysis. On iron of similar analysis, it gives a closer expression of the efficacy of the gasified carbon of the fuel in removing the oxygen from the ore.

2—The calculations involved in figuring the corrected  $\text{CO}/\text{CO}_2$  ratio should be as accurate as possible. Since the answer is in the form of a ratio, the methods used in obtaining all figures should be the same in all cases. They should not vary unless the same answer is obtained.

3—The corrected  $\text{CO}/\text{CO}_2$  ratio probably will show changes in furnace performance quicker than any other method available. Given similar conditions of furnace performance, a 24-hr lapse should show whether any change is or is not beneficial. One decided advantage is that a satisfactory comparison can be made on a furnace when changing ore, fuel, flux, slag volume, moisture in the wind, products, or any variable affecting furnace performance such as filling, shape of combustion zone, or top pressure. In short, factors changing furnace performance can be correlated quicker and better due to the more accurate ratio used for comparison.

4—If large changes are made in iron analysis, addi-

Table VIII. Comparison of Normal and Beneficiated Ores

|                    | Normal Ores  | Beneficiated Ores |
|--------------------|--------------|-------------------|
| Product            | 1324 x 4.066 | 1605 x 3.293      |
| Product            | 5384.4       | 5285.3            |
| Average            |              | 5334.9            |
| Difference         |              | 99.1              |
| Difference/Average |              | 1.84%             |

The above product of the corrected  $\text{CO}/\text{CO}_2$  ratios and the iron production approximate a constant with a swing of 1.84 pct.

|                    |               |               |
|--------------------|---------------|---------------|
| Product            | 1324 x 2.1549 | 1605 x 2.1105 |
| Product            | 2853.1        | 3387.4        |
| Average            |               | 3120.3        |
| Difference         |               | 534.3         |
| Difference/Average |               | 17.12%        |

The above product of the normal  $\text{CO}/\text{CO}_2$  ratios and the iron production approximate a constant with a swing of 17.12 pct.

tional corrections might be necessary to allow for oxygen removed from reduced elements entering the iron. A distinct possibility exists that with due allowance for heats of reaction, almost all furnace products could be placed on a comparable basis.

5—No attempt has been made to introduce too many additional corrections at this time. Subsequent evaluation of the Killian-Joseph corrections should suggest them if needed. For instance the oxygen evolved from the metalloids has not been considered. It is felt that this paper covers sufficient territory at this time.

6—Attention is again called to the fact that the basis for the second correction was first proposed by Dr. T. L. Joseph in his discussion on why the normal  $\text{CO}/\text{CO}_2$  ratio failed.

7—The corrected  $\text{CO}/\text{CO}_2$  ratio as here applied to the furnace performance used, deviates 1.84 pct from being an accurate ratio, compared with a deviation of 17.12 pct with the normal ratio. In the instance used, the corrected  $\text{CO}/\text{CO}_2$  ratio shows one-ninth the divergence of the normal ratio if applied directly to furnace production. Roughly speaking it is nine times as accurate.

8—Attention is again called to the fact that the normal  $\text{CO}/\text{CO}_2$  ratio changed from 2.15 to 2.11 in going from normal to beneficiated ores, while the corrected  $\text{CO}/\text{CO}_2$  ratio changed from 4.066 to 3.293. Thus the normal  $\text{CO}/\text{CO}_2$  ratio was not only worthless, but in this specific case must be considered as definitely misleading. While the normal  $\text{CO}/\text{CO}_2$  ratio tends to hide it, the corrected  $\text{CO}/\text{CO}_2$  ratio expresses the change in the reducing power of the gas which has been utilized by the furnace.

9—In order to have the second portion of this work presented in as clear form as possible, the 0.13 pct  $\text{CH}_4$  in the furnace gases from the normal and beneficiated ores has been omitted from the calculations. A correction similar to, but more complicated than, placing the gas on a hydrogen-free basis would have been necessary. Thus every volume of  $\text{CH}_4$  in the gas would require the deduction of three volumes of  $\text{CO}_2$  and the simultaneous addition of four volumes of  $\text{CO}$  when the correction is made. With 0.13 pct  $\text{CH}_4$  in both gases, this correction was omitted.

10—The corrected  $\text{CO}/\text{CO}_2$  ratio is not a perfect comparison of the working of a furnace and must not be considered as such. It is presented as the simplest and most practical numerical expression of the efficiency of the blast furnace in terms of relative efficiency and relative production.

# Burst Phenomenon in the Martensitic Transformation

by E. S. Machlin and Morris Cohen

The martensite reaction in single crystals and polycrystals of 70 pct Fe-30 pct Ni alloys is shown to be autocatalytic in nature, producing bursts of transformation during cooling. The temperature of the first burst of transformation, called  $M_b$ , occurs below  $M_s$  in these alloys. Experiments were devised to test the athermal embryo and strain embryo theories of martensite nucleation. The results indicate that internal strains, either within the virgin austenite or around existing martensitic plates, control the nucleation process in these alloys. Furthermore, the growth of martensitic plates is not limited by the attainment of an elastic balance with the austenitic matrix, but by the occurrence of plastic deformation at the martensite boundaries which interferes with the propagation mechanism.

IN an investigation of the martensitic habit in single crystals of a 69 pct Fe-31 pct Ni alloy,<sup>1</sup> it was observed that about 25 pct of the austenite transformed during subatmospheric cooling within the time-interval of an audible click. This event proved quite spectacular: The shock wave sent out from the specimen freely suspended on a thread in the refrigerating liquid was occasionally sufficiently intense to shatter the Dewar container and to separate the toluene column in the immersed thermometer. The present investigation was undertaken to determine the kinetics and mechanism of this "burst" type of martensitic reaction.

The analyses of the alloys studied are given in Table I. The composition of the single crystal specimens is designated by alloy A, while the polycrystalline specimens were made of alloys B and C as noted in the text. The single crystals were prepared in a vacuum furnace, using a modified Bridgman technique. Most of these crystals were homogenized by holding for 24 hr at about 1300°C just after solidification. However, it may be emphasized here that the degree of homogenization was not a controlling factor in the subsequent experiments, inasmuch as specimens having different degrees of homogenization yielded the same results. All of the single crystals were fully austenitic as slowly cooled to room temperature.

An illustration of the burst phenomenon is given in Fig. 1, which shows oscillograms of electrical resistivity and temperature vs. time during the continuous quenching of 1/16 in. wire specimens (alloy B) in a dry ice and acetone bath at -77°C. There are at least two observable bursts in this case, as indicated by the sharp decreases of resistance accompanying the sudden formation of substantial quantities of martensite. The thermal arrest during the quench probably corresponds to the larger burst. Usually the bursts are followed by more or less progressive transformation during continuous cooling.

E. S. MACHLIN, formerly with Massachusetts Institute of Technology, is now with the School of Mines, Columbia University, New York, and M. COHEN, Member AIME, is with the Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

Discussion on this paper, TP 3127E, may be sent, 2 copies to AIME by Dec. 1, 1951. Manuscript, April 10, 1951. Detroit Meeting, October 1951.

This paper is based on a thesis submitted by E. S. Machlin in partial fulfillment of the degree of Doctor of Science in Metallurgy to the Massachusetts Institute of Technology, September 1950. The investigation was sponsored by the Office of Naval Research under Contract N5-ori-07814, Task No. XIV, Designation No. NR-031-142.

Fig. 1—Oscillographs recorded during quench of a 70.5 pct Fe-29.5 pct Ni alloy into a  $\text{CO}_2$  and acetone bath at -77°C. Each horizontal interval corresponds to 0.1 sec. a—Change in resistivity of specimen. b—Change in temperature of specimen. In each case, top line corresponds to +25°C, bottom line corresponds to -77°C.

It will also be noted that the resistance continues to decrease after the specimen has reached the bath temperature. This isothermal change denotes the formation of martensite at constant temperature, and will be the subject of another paper.

Examination of fiducial scratches on the surface of a transformed single crystal has shown<sup>2</sup> that the scratches in adjoining nonparallel martensitic plates are usually bent in opposite directions, as though one plate forms in such a way as to relieve the matrix stresses set up by the adjacent plate. This, together with some of the results described in ref. 1,

Table I. Compositions of Alloys Studied, in Percent

| Alloy | Ni       | C     | N     | Mn    | Si   | P     | S     | Cr   |
|-------|----------|-------|-------|-------|------|-------|-------|------|
| A     | 31±0.3   | 0.048 | 0.027 | 0.003 | 0.56 | 0.007 | 0.002 |      |
| B     | 29.5±0.2 | 0.036 | 0.02  | 0.19  | 0.09 | 0.008 | 0.006 |      |
| C     | 19.99    | 0.52  |       | 0.37  | 0.47 | 0.010 | 0.015 | 0.04 |

led to the tentative concept that a cooperative action exists which provides the impetus for much of the transformation that appears during the burst. The following series of experiments were performed in order to test this idea.

## Cooperative Nature of the Burst

Two adjacent disks, 1/8 in. thick x 3/4 in. diam, were cut from a single austenite crystal of alloy A using a jeweler's saw. One of the disks was then cut into 15 parts. Then 12 of the latter pieces and the second disk were austenitized (stress relieved) at 600°C for 30 min and water quenched to room temperature. The temperatures at which the first burst of transformation appeared were determined for

each specimen by cooling below room temperature. The temperature of the first burst of transformation has been termed  $M_b$  to distinguish it from the well-known  $M_s$  temperature, where the first plates of martensite form. The results given in Table II show that  $M_b$  varied from  $-54^\circ$  to  $-78^\circ\text{C}^*$  and that the whole disk transformed within  $2^\circ$  of the highest burst temperature found for the separate parts. Furthermore, the amount of martensite produced at  $M_b$  in the disk and in each of the individual pieces was of the order of 20 to 30 pct. Before examining the significance of these findings, another series of experiments that yielded similar results will be described.

Martensite range curves were determined for bulk specimens of polycrystalline alloys B and C as well as for powders (200 mesh) comprised of filings from these alloys. The purpose of subdividing the polycrystalline specimens into powders was the same as for the single crystal experiments, namely, to eliminate the cooperative effect, if such existed, and to reveal the distribution of transformation among the individual polycrystalline particles. This principle has already been applied to a study of solidification of liquids by Turnbull.<sup>3</sup>

The procedure involved in obtaining the range-curve data was as follows: The specimens were sealed in evacuated Vycor tubes, then austenitized at  $1200^\circ\text{C}$  for 1 hr, quenched in water to room temperature (after which the tubes were broken), and finally cooled to a sequence of subzero temperatures in the martensite range. The amounts of martensite in both the massive and powdered specimens were determined by lineal analysis.<sup>4</sup>

Results for alloy C\*\* are given in Fig. 2. Alloy B yielded similar effects. The range curve for the bulk polycrystalline specimens exhibits a sharp increase in transformation at  $M_b$ , followed by an increase in the amount of transformation (possibly stepwise) with decreasing temperature. The range curve for the powdered samples discloses a gradual increase in amount of transformation with decreasing temperature, without the initial sudden jump found for the bulk specimens. Thus, the subdivision effect re-

Fig. 2—Martensite range curves of bulk and powdered polycrystalline specimens of 79.5 pct Fe-20 pct Ni-0.5 pct C alloy.

ported in Table II for the single crystals is also displayed by the polycrystalline specimens: That is, not all the powder transformed the same amount at the same temperature, but instead there were particles that burst at different temperatures. The number of particles that burst increased with decreasing temperature, until all the particles had undergone a burst.

It was found that the physical subdivision of the whole into parts resulted in less total transformation and a smaller number of martensitic plates, at a given temperature, than would have been obtained for the unseparated whole. The separation eliminates the elastic coupling between the isolated parts, so that no stresses are transmitted from one part to another. Hence, it may be concluded that a cooperative effect exists in the phenomenon of the burst. The formation of a small number of plates, presumably beyond some critical amount or in some critical way, appears to catalyze the further transformation which occurs cataclysmically as a burst in less than  $10^{-4}$  sec.<sup>5</sup>

The burst phenomenon cannot be explained either by the existence of a large number of embryos that are slightly subcritical just above the burst temperature, in accordance with the athermal nucleation concept of Fisher, Hollomon and Turnbull,<sup>6</sup> or by the sudden isothermal formation of a large number of embryos at the burst temperature, in accordance with the thermal nucleation concept of Kurdjumow.<sup>7</sup> This is deduced from the fact that very few of the subdivided parts of the crystals or powders of polycrystals undergo the burst at the same temperature. If it should be argued that the temperature variation of the burst was caused by the samples being too small to be representative and/or that the nickel

content of the alloy varied from part to part, these alternatives may be ruled out by the following:

1—The samples in the single crystal experiments were at least  $\frac{1}{8} \times \frac{1}{8} \times \frac{1}{8}$  in. and hence should have been large enough to contain a representative distribution of embryos. Also the martensitic plates formed therein were not perceptibly controlled by the specimen size, judging from the fact that they were no smaller than in the  $\frac{1}{8}$  in. thick  $\times \frac{3}{4}$  in. diam specimen.

2—The nickel content did not indicate any correlation with the burst temperature as shown by the data of Table IIIa. These results were obtained with a new set of specimens subjected to the same procedure as for the specimens corresponding to Table II.

#### Relation of $M_b$ to $M_s$

Two properties were measured in an attempt to determine whether any transformation took place above  $M_b$ : 1—intensity of magnetization, and 2—electrical resistance. The sensitivity of these methods as used were 1 pct martensite and 0.05 pct martensite, respectively, and hence only the electrical resistance results will be presented here.

The electrical resistance specimens were 1/16 in. diam wires of alloy B. Austenitizing was carried out at 1100°C for 30 min in an atmosphere of prepurified nitrogen, followed by oil quenching to room temperature. A Kelvin double bridge was used for determining the electrical resistance, while the specimens were cooling to subatmospheric temperatures.

Measurements of electrical resistance as a function of temperature yielded curves similar to the one shown in Fig. 3. It is to be noted that the points deviate from a straight line in the temperature

Fig. 4—Upheaval of martensite plate on surface of single crystal of 69 pct Fe-31 pct Ni alloy that had been electropolished prior to subcooling. Note slip in austenite around plate. Oblique illumination. X1500.

range just above  $M_b$ . This result provided the first definite clue that some martensite formation may take place above  $M_b$ .

It seemed worthwhile at this point to determine whether the deviation of the line above  $M_b$  represented a reversible or irreversible process. Accordingly, an electrical resistance vs. temperature curve was run on a specimen to 5° below the temperature at which the curve became nonlinear, but still above the burst temperature. There the cooling was

stopped, the specimen was reheated, and resistance measured as a function of temperature. The heating curve did not retrace the nonlinear curve, but remained quite parallel to and below the linear part of the cooling curve. Thus, the deviation from linearity was not reversible. In fact, subsequent metallographic observations demonstrated conclusively that some martensite actually formed above  $M_b$ . The extent of such transformation was estimated by means of a set of curves of electrical resistance vs. percentage of martensite (each curve corresponding to a given temperature) where lineal analysis was employed for calibration purposes. Using these master curves with linear extrapolation to 0 pct martensite, it was found that the maximum amount of martensite formed above  $M_b$  was approximately 0.5 pct in the alloys under consideration. Repetition of these experiments using precision-length techniques yielded the same results.

The best metallographic procedure for disclosing the martensite formed above  $M_b$  was to electropolish the austenitic specimen prior to the subcooling and to search meticulously for the upheavals of martensite on the unetched surface after the subcooling. An example of such a martensitic upheaval is given in Fig. 4.

With these results, it was clearly demonstrated that  $M_s$  is higher than  $M_b$  for the specific cases investigated. It is conceivable, however, that  $M_s$  may equal  $M_b$  under different experimental conditions.

#### Visual Study of Martensitic Plates

The martensite formed above  $M_b$  appears primarily at the surface of single austenite crystals and at the grain boundaries of polycrystals. In the former case, the martensitic plates exist entirely within the austenite crystal (except where they meet the air surface) and do not require grain boundaries or

b—Plate *b* formed after re-quenching to  $-50.5^{\circ}\text{C}$ . Surface then electropolished and electroetched.

c—Plate *c* formed after re-quenching to  $-51^{\circ}\text{C}$ . Surface then electropolished and electroetched. On re-quenching to  $-51.5^{\circ}\text{C}$ , plates *d*, *e*, and *f* were formed. Micrographs were then taken without any further surface preparation.

Fig. 5—Martensite plates formed above  $M_b$  at surface of single crystal. Vertical plates formed on initial quench to  $-52^{\circ}\text{C}$ . Oblique illumination. X750.

other plates to inhibit their growth. For example, the plate of Fig. 4 was examined not only on the surface shown but after repeated electropolishing and etching to reveal the complete three-dimensional surroundings. The plate extended below the surface for a distance roughly equivalent to its length in the plane of the surface, and there were no grain boundaries or nearby martensitic plates to prevent further growth. In addition, it was observed that subboundaries (veining) and slip lines in the single crystals did not act as noticeable barriers to the growth of martensitic plates. Fig. 4 provides an illustration of a plate that propagated through a veining boundary. These findings are contrary to the postulation that the plates should grow out to boundaries at which resisting stresses can develop.<sup>8</sup>

It was noted in these metallographic studies that the ends of the martensitic plates acted as favored (but not exclusive) nucleation sites for the formation of plates which came into being on further cooling (still above  $M_b$ ). Sequences of this phenomenon

are shown in Figs. 5 and 6. The vertical plates of martensite in Fig. 5a were formed at the surface of a single crystal of austenite during a quench to  $-52^{\circ} \pm 0.5^{\circ}\text{C}$ . This surface was then electropolished at room temperature and lightly etched with Marble's reagent\*\*\* to disclose the etched pattern of the plates. The specimen was then quenched to  $-50^{\circ}\text{C}$ ,  $2^{\circ}\text{C}$  higher than previously,<sup>†</sup> and the thin plates marked "a" appeared. The micrograph in Fig. 5a was taken at this stage.

As a next step, the same specimen was quenched to  $-50.5^{\circ}\text{C}$ , and the plate marked *b* appeared. This is shown in Fig. 5b which was taken after re-electropolishing and electroetching at room temperature. Despite the fact that plate *b* seems to be an extension

\*\*\* Copper sulphate 20 g, concentrated hydrochloric acid 100 ml, water 100 ml, ethyl alcohol 200 ml yields a modified Marble's reagent which is very sensitive to the presence of martensite in this alloy.

† The martensitic transformation in single crystals is quite sensitive to the state of the surface, which accounts for the increment of transformation during the second cooling.

a—Same as Fig. 5c. Micrograph taken at X375 in order to include all of plate *f*.

b—Same as Fig. 5c. Plates *g* and *h* were formed at same time as plates *d*, *e*, and *f*. Micrograph taken at top of original vertical plate. Compare with Fig. 5b. X750.

c—After taking micrograph of Fig. 6b, specimen was lightly etched with Marble's reagent to bring out transformation. Note that lines at sides of plates *g* and *h* have disappeared indicating they are slip lines. X750.

Fig. 6—Martensite plates formed above  $M_b$  at surface of single crystal. Note that, as in Fig. 5, new plates have appeared at ends of existing plates. Oblique illumination.

Fig. 7—Micrograph of a previously electropolished surface after a burst of transformation has occurred. Lines shown in micrograph are slip lines. Bending of slip lines indicates that slip occurred prior to the transformation in such regions. X500.

of plate *a*, there is actually a discontinuity between the two, and *b* must be regarded as a new plate that was nucleated at the end of the existing plate.

The micrograph in Fig. 5c was taken on the same specimen after quenching to  $-51^{\circ}\text{C}$ , electropolishing, electroetching, and requeenching to  $-51.5^{\circ}\text{C}$ , with no further surface treatment. Plate *c*, which is etched in Fig. 5c but not present at all in Fig. 5b, formed during the quench to  $-51^{\circ}\text{C}$ . Plates *d*, *e*, and *f* of Fig. 5c, plates *e* and *f* of Fig. 6a and plates *g* and *h* of Fig. 6b are visible as upheavals, and hence must have formed during the last quench to  $-51.5^{\circ}\text{C}$ . The discontinuous nature of the propagation of successive plates is evident. It is also clear that the later plates may or may not have the same orientation as the existing plates, and that the ends of prior-formed plates are activated regions for the nucleation of new plates. (The different orientations merely represent various permutations of the habit  $\pm \{259\}$ ). These findings are in accord with the previous observation that the burst phenomenon is an autocatalytic reaction.

Examination of Figs. 4 and 6b reveals the presence of fine lines in the austenite around the martensitic plates. In order to determine whether these lines were due to slip or to upheavals of tiny martensitic platelets, the specimen of Fig. 6b was lightly etched with Marble's reagent. The resulting structure, shown in Fig. 6c, indicated no trace of the fine lines, and therefore the latter could not have been caused by martensitic platelets. It may be concluded that the lines were slip lines due to plastic deformation of the austenite. This supports the suggestion of Kurdjumow<sup>7</sup> that plastic flow around the martensite produces a loss of coherency and limits the size of the plates. By the same token, the plate thickness is not controlled by a balance between the driving free energy and elastic restraining energy, and calculations<sup>8</sup> based on such an hypothesis can have little significance, at least for Fe-base alloys in which large transformation strains occur.

Additional evidence contrary to the energy-balance hypothesis was obtained from a study of martensitic plate-thickness vs. temperature in the martensite range, which demonstrated that existing plates do not increase in thickness during cooling. According to the above hypothesis,<sup>8</sup> the plates should thicken by 33 to 700 pct (depending on the extremes

in thermodynamic data found in the literature<sup>9, 10</sup>) on cooling between  $-20^{\circ}$  and  $-90^{\circ}\text{C}$ , but no such change was found. In a few instances, the apparent thickness increased due to the formation of platelets alongside the original plate, but this took place stepwise with decreasing temperature.

The specimen of Figs. 5 and 6 was finally cooled to  $-64^{\circ}\text{C}$  where the burst occurred. A typical region of the resulting upheavals is given in Fig. 7. Clearly, the average thickness of plates formed in the burst is many times larger than that of plates formed above  $M_b$ . This signifies that during the burst the stresses developed at the side-boundaries of the transforming plates are much less for a given plate thickness (and therefore the plates can grow much thicker before plastic flow occurs) than in the case of plates forming above  $M_b$ . The foregoing conclusion seems reasonable in the light of the fact that there are at least four different permutations of the  $\pm \{259\}$  habit<sup>†</sup> which tend to move the adjacent austenite in about the same direction when martensite forms cooperatively along these planes.<sup>1</sup>

Fig. 7 also shows numerous slip lines which are bent where they cross martensite plates. This indicates that extensive slip may take place during the burst in some regions prior to the formation of martensite there. Moreover, it means that such slip lines are not sufficiently strong barriers to prevent the propagation of martensite.

Two important questions are raised by the above results: 1—What is the criterion for the triggering of the burst? 2—What is the significance of the fact that the ends of existing plates are favored nucleation sites for new plates?

A tentative answer to the first question is obtained from consideration of some additional experiments. It has been found that room temperature alteration of the state of the surface of a single crystal after quenching to a given subatmospheric temperature may induce a burst on requeenching to that same temperature. Furthermore, it has been noticed that bursts may occur isothermally in polycrystalline specimens after some time at a subzero temperature (held constant within  $\pm 0.2^{\circ}\text{C}$ ), either with or without a measurable change in resistivity occurring prior to the burst at that temperature. It has also been observed that rapid quenching of 1/16 in. diam polycrystalline wires into a bath at  $-77^{\circ}\text{C}$  can depress  $M_b$  by about  $20^{\circ}\text{C}$  as compared to slow cooling. These findings indicate that the triggering of the burst does not take place at a characteristic temperature for the alloy at hand, but is sensitive to other experimental variables.

In the light of ref. 1, a possible criterion for the onset of the burst is that a number of plates, which have the same direction of adjacent austenite motion and which bound the same region of austenite, must be nucleated almost simultaneously. Under these conditions, it appears that stresses are transferred to other austenite regions where new plates can be activated. Undoubtedly, the momentum of the process helps to increase these stresses. The activation can occur either at existing regions of strain or even in previously strain-free regions, if sufficient stress of the proper direction is developed.

This mechanism for producing the burst leads to the observed structure-sensitivity of the burst tem-

<sup>†</sup> In systems having the  $\pm \{225\}$  habit, the degree of cooperation as measured by the number of austenite directions of motion within the same solid angle used for the  $\pm \{259\}$  case, is roughly about one half that for the latter.

perature because the probability of activating an embryo is affected by the prior state of internal strain at the embryo. The mechanism also provides for autocatalytic action through the dynamic as well as static stresses developed by the cooperative displacements. Consequently, it can be predicted that bursts will not occur as markedly in other systems where the crystallography of the transformation happens to permit less cooperation than in these alloys. For example, the cooperative effect is not so great for systems with  $\{225\}$ † habits as for systems with  $\{259\}$  habits. Thus, it may be expected that the burst phenomenon will not be so prominent in ordinary steels as in these Fe-Ni alloys.

Let us now consider the significance of the preferential nucleation of martensite above  $M_s$  at the ends of isolated martensite plates. It is very likely that the magnitude of the internal stress in the austenite bounding an isolated martensite plate is largest at the rim of the plate. The consequence of this situation can be interpreted in at least two ways. According to the theory of martensite nucleation via athermal<sup>8</sup> embryos of the martensitic phase, stress should act to decrease the critical size of the embryos, and hence stressed regions should be favored sites for nucleation. However, inasmuch as the volume of the highly stressed region about the rim of an isolated martensite plate is extremely small, either the critical size would have to be an exceptionally sensitive function of stress, or the concentration of athermal embryos would have to be very high. An alternate interpretation, according to the theory of martensite nucleation via strain embryos,<sup>2</sup> is that the region of internal stress at the rim becomes an embryonic region of large strain and appropriate direction of strain to nucleate additional martensite. Although there does not appear to be any way of positively distinguishing between these theories from the data obtained so far, an important conclusion can be drawn; that is, whether the new martensite is nucleated at existing martensite rims by athermal embryos or not, the nucleation there is controlled by the internal strains and not by the distribution of athermal embryos. Inasmuch as any real specimen contains many internal strains, this conclusion might be generalized to include internal strains other than those at the martensite plates. It is important to note here that the plates appearing above  $M_s$  are not nucleated exclusively by the prior-formed martensite. This applies to the plate in Fig. 4 and, of course, to the original plates in Fig. 5.

Further experimental verification of the above deduction as applied to the general transformation is given in the next section.

### Athermal Nucleation

The aspect of the athermal nucleation theory that was checked was the supposed role of an equilibrium statistical-mechanical distribution of martensitic embryos at the austenitizing temperature. According to this concept, the amount of martensite produced for a given temperature in the martensitic range, and for a given grain size, is a function of the martensitic embryo distribution, and hence of the austenitizing temperature. Thus, one series of specimens was subjected to the cycle illustrated in Fig. 8a, another to the cycle of Fig. 8b, and a third to the cycle of Fig. 8c. In all instances, the heating

Fig. 8—Temperature-time cycle to determine effect of austenitizing temperature on martensite range curve.

for 1 hr at 1200°C “set” the grain size which did not change during the subsequent treatments. In case b, the temperature was then lowered to 900° for 24 hr to establish an embryo distribution characteristic of this temperature. In case c, the holding time at 600°C was for one week. In cases a and b, the quench to room temperature was interrupted momentarily at 600°C so that the final quenching stresses would be the same in the three series, after which the subzero transformation was determined immediately. Direct quenching was also conducted from 1200° and 900°C to room temperature, but there was no effect on the results and hence the interruption at 600°C was actually not a factor.

The results obtained from these experiments, given in Fig. 9, show that the amount of transformed phase is independent of the austenitizing temperature, grain size being maintained constant. It may therefore be concluded that athermal embryos of the martensitic phase, if they exist at all, do not activate the martensitic transformation in these Fe-Ni alloys. It may further be inferred, from the generality of the concept, that this negative conclusion also applies to other materials.

### Experiments Relating to Strain Embryos

Having demonstrated that the possible existence of statistical distributions of martensitic embryos in the austenitic phase was irrelevant to the problem under consideration, it appeared worthwhile to investigate the alternate suggestion that the embryos for the martensitic reaction are comprised of regions of internal strain in the austenite<sup>2</sup> (e.g., accidental lattice disturbances or dislocations). On this basis, it would be predicted that a cold-worked sample should undergo transformation at a higher temperature than a non-cold-worked sample. Moreover, specimens as cut from a single-crystal ingot should transform at higher temperatures than similar specimens after stress relieving. Because plastic deformation of polycrystals may introduce barriers to the transformation as well as the higher energy strain embryos being sought, it was decided to per-

Fig. 9—Martensite range curve for 70.5 pct Fe-29.5 pct Ni alloy. Austenitizing temperature varied according to cycles in Fig. 8.

† The exact agreement of some of the data in Fig. 9 is considered fortuitous.

Fig. 10—Effect of plastic deformation performed above  $M_d$  ( $60^\circ\text{C}$ ) upon subsequent martensite transformation in 70.5 pct Fe-29.5 pct Ni alloy.

form these experiments first with single crystals of alloy A.

Several cube specimens,  $\frac{1}{4}$  in. on a side, were cut from a single crystal of austenite, then stress relieved at  $600^\circ\text{C}$ , and refrigerated to ascertain the  $M_b$  temperatures. Similar stress-relieved specimens were compressed by 10 to 50 pct at a temperature above  $M_d$  ( $\sim 60^\circ\text{C}$ ), and the  $M_b$  temperatures were determined. Two single-crystal ingots were used. The results with specimens from one ingot (Table III) showed that the average  $M_b$  temperature was raised from  $-63^\circ$  to  $-46^\circ\text{C}$  by the cold working, and that the inherent spread in these values was markedly reduced. For specimens from the second ingot, the average  $M_b$  temperature was raised from  $-55^\circ$  to  $-47^\circ\text{C}$  by cold working.

Further verification was obtained in the following way: A  $\frac{1}{8}$  in. cube single crystal was cooled to as low a temperature as possible, called the reference temperature, above  $M_b$ . Then the specimen was heated above the  $M_d$  temperature, compressed 10 pct and cooled back to the reference temperature. If no burst occurred during this cooling, the specimen was heated back above  $M_d$ , compressed further, and the cycle repeated to determine whether a burst would ultimately occur on cooling to the reference temperature. The results definitely proved that plastic deformation above  $M_d$  raises the burst temperature. For example, compression in the range of 10 to 35 pct raised  $M_b$   $4.5^\circ$  to  $7.5^\circ\text{C}$  above the reference temperature from its previous level below the reference temperature.

Another manifestation of this phenomenon was shown by comparison of the  $M_b$  values for specimens as cut from the single-crystal ingot with those for similar specimens after stress relieving at  $600^\circ\text{C}$ . The average  $M_b$  of the annealed crystals was  $15^\circ\text{C}$  lower than the average  $M_b$  of the as-cut crystals. The strain-embryo concept is consistent with all these experiments on single crystals.

Previous investigators<sup>11, 12</sup> have reported that plastic deformation of polycrystalline alloys usually has a stabilizing effect on the subsequent transfor-

mation. This trend is contrary to the results just described for single crystals. In order to ascertain the reason for the anomaly, experiments were performed with polycrystalline wires of alloy B in the following way. Several wires,  $\frac{1}{16}$  in. diam, were first austenitized in an evacuated Vycor tube at  $1100^\circ\text{C}$  for 30 min, then quenched in water to room temperature. Reductions in area of 0, 10, 20, 30, and 40 pct were achieved by drawing the wires through dies while kept above  $M_d$  ( $\sim 60^\circ\text{C}$ ). Immediately after this plastic deformation, each specimen was subcooled, and the electrical resistance measured as a function of the temperature.

The results of these experiments can be summarized as follows: With increasing amounts of plastic deformation (up to 40 pct reduction in area) above  $M_d$ : 1— $M_s$  was raised progressively (40 pct reduction in area corresponded to an increase in  $M_s$  of about  $17^\circ\text{C}$ ). 2— $M_b$  was first increased slightly, then decreased. 3—At temperatures somewhat below  $M_b$  of the nondeformed specimen, the amount of transformation was less, the greater the amount of deformation. These characteristics are illustrated in Fig. 10, which shows the temperature-resistivity curves for specimens having 0 and 40 pct reduction in area subsequent to austenitizing.

The above relationships clearly indicate that there are two opposing effects of prior plastic deformation on the martensite transformation during subsequent cooling. The first effect is an increase in the magnitude of the submicroscopic internal strains, and thus martensite can be nucleated at higher temperatures. This accounts for the fact that  $M_s$  increases with the extent of plastic deformation. The second effect of plastic deformation, appearing primarily in polycrystalline alloys, is to "subdivide" the grains into smaller units as a result of the inhomogeneous nature of the deformation (the formation of kink bands and deformation bands provides an effectively finer grain size). Because the average length of plate formed from a given strain embryo is smaller in the "subdivided" grains, the volume of martensite per activated embryo would be expected to decrease with increasing plastic deformation. Hence, even though there is an increase in the number of embryos activated at any given temperature, the actual amount of transformation may be less. The net result of plastic deformation is a combination of these two opposing effects. A somewhat similar conclusion has been reached by Kurdjumow<sup>13</sup> in his studies on the influence of prior plastic deformation on the subsequent isothermal martensite transformation.

The two opposing trends also bear directly on the  $M_s$  temperature. As  $M_s$  is raised by plastic deformation,  $M_b$  is also raised; but with increasing amounts of deformation as applied to polycrystals, the partitioning of the austenite caused by inhomogeneous deformation makes it progressively more difficult for the burst to occur. Consequently,  $M_b$  then begins to drop. This characteristic may be regarded as a grain-size effect, which is discussed in the next section.

### Constraint and Grain Size Effects

The explanation of the burst phenomenon herein presented predicts that if restraint is provided at the boundaries of the single crystal then the burst temperature should be depressed, but not necessarily the  $M_s$  temperature. To test this prediction the following experiments were performed: Single crystals of alloy A,  $\frac{1}{16} \times \frac{1}{8} \times \frac{1}{8}$  in., which had been serrated on their faces to provide a good mechanical bonding

<sup>††</sup>  $M_d$  is the temperature above which austenite is not converted into martensite by plastic deformation.<sup>11</sup>

surface and etched for 1 hr to remove the cold-worked surface layer, were stress relieved at 600°C and mounted in bakelite with a 1/16x1/8 in. polished face exposed. Control specimens from adjacent positions in the single-crystal ingot were also mounted in bakelite in exactly the same manner, then removed carefully from the bakelite by cutting the bakelite away from the sides with a jeweler's saw. The  $M_s$  temperatures of the control specimens were determined by immersing in cold baths at lower and lower temperatures until the burst took place. This was detected audibly by the "click" as well as by the visible evolution of bubbles in the bath due to the heat of transformation. Also after heating back to room temperature, the martensite could be seen by microscopic examination on the polished surface.

Before the burst temperatures of the bakelite-constrained specimens were determined, a run was conducted to establish the time required for the specimen to reach within 1° of the bath temperature. It was found that about 3 min were required. Accordingly, the bakelite-constrained specimens were kept in the bath for 6 min in order to insure that the bath temperature was reached. Exactly the same methods were used for observing the burst in the bakelite-constrained specimens as in the case of the control specimens. The results obtained are given in Table IV.

It is evident that the bakelite-constraint caused a lowering of the burst temperature. The extent of depression of  $M_b$  ranged from about 15° to 20°C. (The good reproducibility of burst temperatures for the control specimens was undoubtedly due to the fact that the mounting in bakelite introduced some strain into the specimens.)

According to the ideas presented here to account for the burst phenomenon, there should be small amounts of martensite in the constrained specimens at a temperature above their  $M_b$  and below the  $M_s$  of the control specimens. When painstaking care was taken in preparing and examining the surfaces of the specimens, such small amounts of transformation were detected.

A further prediction stemming from this picture of burst formation is that, if two different sizes of specimens are constrained, the smaller specimens should burst at the lower temperature. This follows from the fact that with a given surface constraint, more resistance to the burst transformation is generated in the smaller specimen than in the larger one, other things being equal. To test this consequence, two sizes of single crystals were mounted in bakelite. One was 1/4x1/4x1/4 in. and the other 1/32x1/8x1/8 in. The average  $M_b$  values so obtained were: -38.5°C (free control specimen), -50.5°C (large constrained specimen), and -55°C (small constrained specimen).<sup>‡‡</sup>

Constraint may also be achieved if the crystal is surrounded by other crystals in the form of a polycrystalline aggregate. In order for the chain of transformation to continue, the austenite along the

Fig. 11—Electrical resistance vs. temperature curves for specimens having A.S.T.M. No. 4-5 and A.S.T.M. No. 9 grain size. Alloy of 70.5 pct Fe-29.5 pct Ni.

side of the transforming plate must be able to move. If it is constrained by a rigid material such as bakelite, then a chain of transformation, once started, would be quickly stopped by the resistance to motion developed at the boundaries, and the temperature would have to be decreased to overcome this resistance. In a similar way, grains of different orientation at the boundaries of the crystal can act as constraints, from which it follows that the burst temperature should decrease with decreasing grain size, even though the  $M_s$  temperature may not be appreciably affected.

To check the predicted effect of grain size, electrical resistance measurements were made on 1/16 in. diam wires of alloy B having grain sizes of ASTM No. 9 and ASTM No. 4-5. The first series of specimens was austenitized at 760°C for 20 min and the second series was austenitized at 1100°C for 1 hr. All of the specimens were oil quenched to room temperature. The results of these measurements are given in Fig. 11.

Two points are immediately clear. One is that the  $M_b$  of the fine-grained material is about 40°C lower than that of the coarse-grained material. The other is that the deviation from linearity in the resistance vs. temperature curves starts at about the same temperature in both cases. Subsequent metallographic investigation showed that the deviation from linearity is associated with the formation of martensite plates above  $M_b$ .

This phenomenon was checked in still another way. Length measurements made during subcooling and reheating in a high precision linear coefficient of expansion apparatus<sup>14</sup> agreed unambiguously with the electrical resistance determinations in disclosing the existence of transformation above  $M_b$  in both the coarse-grained and fine-grained material. Thus, the predictions of grain size upon both  $M_b$  and the transformation above  $M_b$  were confirmed. According to these results,  $M_s$  is not sensitive to grain size, if it is defined as the temperature at which the martensitic reaction starts.

To account for the grain-size effect on  $M_b$  on the basis of the nucleation and growth theory,<sup>8</sup> it is

<sup>‡‡</sup> These three  $M_b$  values happen to be higher than those given in the previous tables because of an unusually low Ni content.

Table IV.  $M_b$  Values for Constrained vs. Free Specimens

| $M_b$ , °C   |             |                |
|--------------|-------------|----------------|
| Free Control | Constrained | Difference, °C |
| -51.5        | -67.5       | 16             |
| -50          | -70         | 20             |
| -51          | -70         | 19             |
| -51          | -72         | 21             |

necessary to assume that, with decreasing grain size, the plates become thinner in proportion to their decreasing length, and hence become more difficult to detect under the microscope. However, no such dependence of thickness on length was found. Within a very wide range of grain sizes,§§ the plates formed at  $M_b$  were comparatively constant in width, despite enormous differences in length.

It was observed that the amount of transformation involved in the burst often decreased with decreasing grain size and that the transformation sometimes occurred isothermally over a measurable period of time. This phenomenon will be discussed in another paper.

### Summary and Conclusions

The first substantial ( $> \frac{1}{2}$  pct) amount of transformation in 70 pct Fe-30 pct Ni alloys occurs within the interval of an audible click at a temperature called  $M_b$ . This phenomenon, designated as a burst, was investigated experimentally using both single and polycrystalline specimens with the following results:

1—The reaction occurring during the burst is autocatalytic, that is, the first transformation to appear in the burst provides the impetus for the nucleation of succeeding plates and so on.

2—Martensite forms in amounts up to  $\frac{1}{2}$  pct above  $M_b$ , ( $M_b$  is lower than or equal to  $M_s$ ) and new plates are nucleated preferentially at the rims of previously formed plates on decreasing the temperature.

3—Plastic deformation (slip) takes place locally at the martensite-austenite interface in plates formed above  $M_b$ , while substantial amounts of widely dispersed slip occur in the austenite during the burst.

4—The thickness of plates formed above  $M_b$  is very much less than that of plates formed during the burst.

5—Constraint to change-of-shape as offered by bakelite depresses  $M_b$  but not  $M_s$ , and a decrease in the size of the specimen being constrained enhances the depression of  $M_b$ .

6—Decrease in grain size depresses  $M_b$ , but does not measurably affect  $M_s$ .

7—Prior plastic deformation in single crystals raises  $M_s$  and  $M_b$ , and reduces markedly the range of scatter of  $M_b$  values. Prior plastic deformation in polycrystals raises  $M_s$ , first raises then lowers  $M_b$ , and decreases total amount of transformation measured below the  $M_b$  for zero deformation.

Additional experiments were conducted to check the validity of the nucleation and growth theory as applied to the burst phenomenon, with the following results:

1—Once formed, the martensitic plates do not thicken with decreasing temperature, as required by this theory.

2—The martensite range curve below  $M_b$  is insensitive to the austenitizing temperature for the Fe-Ni alloys, which demonstrates the independence of the transformation upon distributions of athermal martensite embryos.

3—The grain size explanation based on nucleation and growth is invalid for two reasons: (a) Plates can exist which are not bounded at the ends by existing plates, grain boundaries or other such obstructions. (b) A direct dependence of plate thick-

ness to length is predicted by the theory, and is not found when the grain size is decreased.

4—The concept of loss of coherency due to plastic flow in limiting the size of plates, as proposed by Kurdjumow, has been found to be consistent with experiment.

It is concluded that regions of internal strain are preferential sites for nucleation of martensite in these alloys. Two such regions are the internal strains within the virgin austenite and the internal strains at existing martensite plates. It appears that the nucleation is more sensitive to the state of strain than to variations in composition.

A tentative explanation for the burst phenomenon has been presented. Use is made of the cooperative nature of the reaction in these alloys to nucleate new plates and thus generate a chain of transformation.

The possibility exists that many martensitic transformations involve bursts, to a greater or lesser extent. If this proves to be the case, the burst phenomenon may provide a new basis for understanding important features of the martensitic transformation.

# Fundamental Effects of Cold Working on the Creep Resistance of an Austenitic Alloy

by D. N. Frey and J. W. Freeman

**Fundamental reasons for the improvement in creep resistance of an austenitic alloy by cold working were investigated mainly by X-ray diffraction. The creep resistance was found to be improved by the internal stresses in the lattice of the alloy induced by the cold work.**

**T**HIS investigation was concerned with the fundamental reasons for improvement in creep resistance of an austenitic alloy as a result of cold working. Also, the investigation was carried out to elucidate the conditions under which cold working could be expected to improve the creep resistance.

To achieve these ends, creep resistance and internal structure were correlated for a variety of cold-worked conditions. Since the aim of the investigation was not to obtain specific and extensive information on any one alloy, creep testing was done with a single stress at 1200°F. Structural studies were carried out primarily with X-ray diffraction characteristics. The alloy used, low carbon N-155, was selected on the basis of being representative of at least some of the alloys used in gas turbines.

Low carbon N-155 alloy in the form of 7/8-in. sq bar stock was used in this investigation. The chemical composition, in percent, was: C, 0.13; Mn, 1.43; Si, 0.34; Cr, 20.73; Ni, 18.92; Co, 19.65; Mo, 3.05; W, 1.98; Cb, 0.98; N, 0.14; and Fe, balance.

The bar stock was produced from a 13-in. sq billet, finished to 7/8 in. round cornered square between 2060° and 1910°F.

---

Prior to use in this particular investigation, the bar stock was solution-treated 1 hr at 2200°F and water quenched. This procedure was used in order to put the stock in a condition where effects of prior processing were minimized.

## Experimental Procedure

The specific approach to the problem was two-fold. First, the influence of cold working, under various conditions, on the creep rate under a single stress at 1200°F and on the internal structure was in part determined. Second, the effect of annealing at various times and temperatures on the creep rate and internal structure of the cold-worked samples was in part evaluated. The first step was basic to the investigation—creep resistance and structure were to be correlated. The second step was taken to see if the annealed samples showed some internal changes which could also be correlated with changes in creep resistance. This it was felt would facilitate solution of the basic problem.

The creep and structural studies were carried out on samples reduced approximately 5, 15, and 40 pct at room temperature and 15 pct at temperatures up to 2200°F. Annealing of various of the samples was done at 1200°, 1400°, 1600°, and 1800°F for time periods up to 1000 hr. Studies of the annealed samples were concentrated on materials rolled approximately 5, 15, and 40 pct at room temperature and 15 pct at 1400°F. The creep tests were carried out at 1200°F under 40,000 psi, the latter being approximately the 1000 hr rupture stress of the material

Fig. 1—Effect of rolling temperature upon microstructure of solution-treated low carbon N-155 alloy reduced 15 pct. Electrolytic chromic acid etch. X1000. Area reduced approximately 70 pct for reproduction.

cold reduced 15 pct. No transient creep was observed, and all tests were run for time periods of from 200 to 500 hr, which was sufficient time to establish the steady state creep rate. All creep data are reported in terms of this steady state rate. The estimated accuracy of these rates was  $\pm 40$  pct.

The structural effects of cold working were studied primarily by X-ray diffraction, although microscopic examination, both optical and electronic, was also used. For the diffraction work, surfaces normal to the bar axis were prepared by electrolytic removal of a minimum of 0.020 in. of metal. This was done to avoid artificially cold-worked metal produced by the sample preparation process itself. Conventional metallographic methods were employed, including the use of uranium shadow-cast Formvar replicas in the electron microscope.

Previous work has shown that broadening of diffraction lines occurs as a result of cold working.<sup>1</sup> This has been ascribed both to particle size broadening from fragmentation of the grains and to a distribution of lattice parameters resulting from residual elastic stresses. It was felt that either effect would be important as far as creep resistance was concerned, and accordingly the width of the (220) line of the austenite was photographically recorded as a function of the various rolling and heat treatments. Chromium radiation was used to eliminate fluorescent effects, and with this radiation the (220) line was at  $67^\circ \theta$ , where fair resolution was obtained. The specimen was mounted normal to the X-ray beam and rotated slowly about an axis parallel to, but offset from the X-ray beam. This latter was occasioned by the desire to cover the largest possible

area on the sample surface (cover more grains), and thus obtain diffraction lines with uniform blackening along the diffraction cone.

The width of the (220) line was then taken at a density half way between that of the top and bottom of the line. Correction for instrumental broadening was done by the method of Warren<sup>2</sup> and by further assuming that the broadness of the (220) line from the solution-treated sample was due entirely to instrumental broadening and using it as the instrumental broadening factor in Warren's formula. All broadening data reported thus are relative to the solution-treated sample. The reproducibility of line widths was not better than  $\pm 10$  pct.

As an aid to determining the basic cause of the line broadening observed, integrated intensity measurements were made on the (111) line of some of the cold-rolled and cold-rolled and annealed samples. Here it was anticipated that extinction\* effects would be of major interest. Inasmuch as the lowest order line shows maximum intensity variation with variation in amount of extinction, the (111) line was used. In particular, it was necessary to determine the variation of (111) line intensity with variation of the angle between the (111) planes contributing to the intensity measurements and the rolling direction in the bar. For this, samples were mounted in a Schultz fixture<sup>3</sup> and placed in the Norelco spectrometer, where intensity measurements were taken at  $5^\circ$  or  $10^\circ$  intervals from  $0^\circ$  to  $90^\circ$  with respect to the rolling direction. To cover this range from  $0^\circ$  to  $90^\circ$ , two sample surfaces were used—one parallel and one normal to the rolling direction. Data were taken from each of these samples over a  $50^\circ$  range. This was necessitated by the fact that Schultz's method breaks down over an angular range of more than about  $50^\circ$ . Over the  $50^\circ$  range used, checks were made with randomly oriented samples to insure the applicability of Schultz's method. A standard of comparison for these intensity measurements was a randomly oriented powder compact made of low carbon N-155 filings prepared so that extinction was believed negligible.

### Structural Alterations as a Result of Cold Working

From a microstructural standpoint little change was observed in samples rolled at room temperature until reductions of the order of 15 pct were reached, at which reduction a very few slip lines or bands

Fig. 2—Effect of reduction at  $80^\circ\text{F}$  on width of (220) line of solution-treated low carbon N-155 alloy.

\* Extinction is the loss of intensity of the diffracted beam due to increasing loss of energy in the primary beam as diffraction itself occurs.

could be observed in polished and rather heavily etched samples. Increasing degree of reduction resulted in greater density of such lines, at least up to reductions of 40 pct.

Increase in the rolling temperature with the degree of reduction held constant at 15 pct resulted in several microstructural changes. From 80° to 1800°F, the grains become more clearly outlined, with possibly some precipitate actually formed at the boundaries at the higher temperatures, see Fig. 1. The change was similar to that obtained when solution-treated material is simply heated at the various rolling temperatures for about 1 hr. After rolling at 2200°F, recrystallization was evident, see Fig. 1. A check on material rolled at 2050°F revealed no recrystallization; it appeared much the same as material rolled at 1800°F. The simultaneous recrystallization temperature† of low carbon N-155 for reductions of 15 pct may thus be placed between 2050° and 2200°F. Greater reductions would probably lower this temperature.

For an interpretation of the widening of the (220) line after rolling, see Fig. 2, reference should again be made to the two possible causes of line broadening due to "cold" work. They are fragmentation of the matrix into crystallites which must have thicknesses less than 1000Å to cause broadening, or the introduction of a range of interplanar spacings, (100) spacings in this case, in turn due to the presence of residual elastic stresses.

In order to separate these two causes of line broadening, use was made of the fact that if the observed broadening were due to crystallites, the crystallites would have to be so small as to preclude any extinction being present. Accordingly the first step in the separation of the two causes of line broadening was to make measurements of the (111) line integrated intensity in order to determine the extinction coefficients‡ of cold-rolled material.

However, before these intensities could be interpreted in terms of extinction coefficients a further complication had to be considered. An intensity increase could be due not only to reduction in extinction, but also to preferred orientation of the crystallites. This latter would act to increase the intensity of various diffraction lines in certain directions relative to the bar axis, such increase not having any relation to a decrease in extinction.

Fig. 3 shows a more detailed study of the intensity of the (111) line at various angles to the rolling direction of materials reduced 15 and 40 pct at 80°F. The curves of Fig. 3 may be taken as representing the relative number of crystallites having the various indicated orientations with respect to the bar (rolling) axis. Further study showed that the preferred orientation was of the "fibred" type with two components (111) and (100). The crystallite distribution about any axis parallel with the bar axis was found to be random. In order to obtain the change in (111) line intensity due to rolling and corrected for the preferred crystallite orientation, use was made of an important feature of Fig. 3. With no change in extinction, the areas of the curves from 0° to 90°, relative to the rolling direction, would re-

Fig. 3—Effect of rolling at 80°F on (111) intensity at indicated angles with the rolling direction of solution-treated low carbon N-155 alloy.

main constant to a very close degree, irrespective of whether the fibred orientation is present or not. Thus, any change in this area is due to extinction effects. For the particular curves of Fig. 3 the height of a rectangle running from 0° to 90° equalling the above-mentioned area would give the (111) line intensity, relative to the extinctionless low carbon N-155 powder compact, of a material having the same crystallite size as the rolled bars but with the crystallites completely random.

Construction of such rectangles was carried out on Fig. 3. For the material rolled 15 pct at 80°F, the resulting (111) intensity relative to the standard was 0.80 and for the material rolled 40 pct, 1.05. The same figure for the plain solution-treated, low carbon N-155 was 0.77. The estimated accuracy for all of these figures was  $\pm 5$  pct.

Since the standard of comparison for the intensity measurements on Fig. 3 was powdered low carbon N-155 with no extinction, the above figures represent extinction coefficients. It is obvious therefore, that rolling 15 pct hardly reduced extinction in low carbon N-155 over what it was without rolling, while rolling 40 pct eliminated extinction at least to within the experimental error.

If these values at the extinction coefficients are entered into the Darwin formula for extinction as a function of crystallite size, it is found that the as-solution-treated low carbon N-155 and the stock rolled 15 pct had crystallite sizes of the order of  $10^{-4}$  cm, while all that can be said for the stock rolled 40 pct is that its average crystallite size was probably less than  $10^{-5}$  cm.

Going back to the original problem of separating particle size broadening from residual strain broad-

Fig. 4—Effect of rolling temperature on width of (220) line of solution-treated low carbon N-155 alloy reduced 15 pct.

† The simultaneous recrystallization temperature is defined as the temperature of rolling or forging, where recrystallization takes place during or just after working, as evidenced by a finer grain size after cool down than was present prior to working.

‡ The extinction coefficient is here defined as the ratio of the observed (111) integrated intensity to the (111) integrated intensity from a powdered sample of low carbon N-155 believed to have no extinction.

Fig. 5—Effect of annealing on width of (220) line of solution-treated low carbon N-155 alloy reduced 13 pct at 80°F.

ening, the Scherrer formula shows that small particle line broadening is negligible with particles greater than  $10^{-5}$  cm, and so particle broadening was certainly absent in solution-treated low carbon N-155 cold reduced up to 15 pct and of unknown proportions in the material reduced 40 pct. It can thus be concluded that for a cold reduction of 15 pct, the line broadening which occurred was due entirely to residual elastic strains, while the line broadening in samples reduced 40 pct could be due in part to small particle size but not very probably. Accordingly, line widths shown in Figs. 2 and 4 may be considered as indicating some average value of the internal "locked up" stresses present after the various treatments indicated.

Fig. 2 indicates that the internal stresses did not increase uniformly with degree of reduction, but rather that the internal stresses apparently would reach a maximum value independent of further reduction. Such results have been noted before by many investigators.

Fig. 4 shows that rolling 15 pct up to temperatures of approximately 1500°F resulted in the same average internal stress. Increasing the temperature of reduction past this point reduced the internal stresses, and rolling at temperatures of about 2200°F resulted in practically no residual internal stresses. It appears that the amount of relaxation of the internal stresses occurring during or just after the rolling operation (during cool down) is the factor which limits the line widths obtainable at the higher rolling temperatures.

Microstructural examination of all the various annealed samples revealed that only the material reduced 40 pct at 80°F recrystallized. This recrystallization started after about 10 hr at 1600°F and was

Fig. 6—Effect of annealing on width of (220) line of solution-treated low carbon N-155 alloy reduced 40 pct at 80°F.

complete after 1000 hr at 1600°F. It was completed at 1800°F in less than 10 hr. The recrystallized texture was of the same general type as existed before recrystallization.

Fig. 5 is typical of the effects of annealing on the (220) line width of all stock reduced 15 pct at temperatures from 80° to 1400°F. Similar results were had for the stock rolled 5 pct at 80°F—line widths of course being at correspondingly lower values, for the same annealing times and temperatures. Reduction of the (220) line widths may be interpreted as the result of internal stress relaxation during the annealing process. It should also be emphasized that this reduction is a recovery phenomenon occurring before recrystallization as the microstructural examination of annealed samples showed.

Comparison of Fig. 6, indicating the effects of annealing on the (220) line of the material rolled 40 pct at 80°F with Fig. 5 shows that 40 pct reduction resulted in significant line sharpening at 1200°F while 15 pct reduction did not. Apparently, the greater the magnitude of the internal stress, the

Fig. 7—Effect of reduction at 80°F on creep rates of solution-treated low carbon N-155 alloy under 50,000 psi at 1200°F.

lower the temperature at which effective relaxation occurs. This reduction of stability of the cold-worked structure with greater degree of cold working seems well substantiated by other investigators of recrystallization phenomena.

### Effects of Cold Working on Creep Resistance

Fig. 7 shows a maximum amount of creep resistance with reduction of the order of 25 pct and that further reduction resulted in either no further improvement of creep resistance or possibly an actual reduction. These results probably hold only for temperatures near 1200°F and in all probability would change for other temperatures of creep testing.<sup>4</sup> While this maximum effect of rolling on creep resistance was present, Fig. 2 indicates essentially that the internal stresses continued to increase with amount of rolling to at least 40 pct reduction.

Fig. 8 shows that the temperature of reduction had small effect on creep resistance under the conditions of testing at 1200°F, unless rolling temperatures greater than about 1500°F were used. For rolling temperatures greater than this, the creep resistance dropped off sharply. Fig. 4 indicates that this drop in creep resistance corresponded closely with the drop in line width.

Fig. 9 shows a typical relationship between creep resistance and annealing. Practically identical results were obtained for material rolled 15 pct at

1400°F. Creep rates for any given anneal after 5 pct reduction at 80°F were somewhat higher than those shown on Fig. 9, while creep rates for the material reduced 40 pct at 80°F were roughly similar for any given anneal to those on Fig. 9.

When comparison of the creep data obtained from the annealed samples was made with the line width data obtained from samples given the same anneal, it was apparent that a correlation between creep rate and line width might exist, but with the creep rate decreasing very rapidly with decreasing line width. This was also evident from comparison of the data on Figs. 3 and 4.

With this in mind, a correlation of the logarithm of the creep rate and the line width for both rolled, and rolled and annealed samples was tried with the result shown on Fig. 10. Considering the possible errors in measuring creep rates and line widths, most points fall no further off the mean line than could be accounted for by experimental error.

Some comment on the significance of this correlation can be made. If the Eyring reaction rate theory for creep is extended to include some average in-

Fig. 8—Effect of rolling temperature on creep rate under 50,000 psi at 1200°F of solution-treated low carbon N-155 alloy reduced 15 pct.

ternal stress, the correlation shown on Fig. 10 can be predicted.

The appropriate expression from the theory for metallic creep appears to be:

$$\dot{\epsilon} = \text{constant}_1 \times T \times e^{-\frac{\Delta F}{RT}} \sinh \frac{\text{constant}_2 \sigma}{RT} \quad [1]$$

where  $\dot{\epsilon}$  is the creep rate at temperature  $T$  and stress  $\sigma$ ,  $\Delta F$  the free energy for activation of the fundamental unit of creep, and  $R$  the gas constant. When considering materials with internal stresses, satisfaction of equilibrium conditions results in the stresses appearing in regions of positive and negative sense. Thus in alternating regions the sense of the internal stress will be opposite to the sense of the applied stress and in the remaining regions it will be the same. However, if one assumes that the periodicity of these alternating stresses meets certain requirements,<sup>8</sup> the regions of internal stress opposite to the sense of the applied stress will control the creep rate. For these regions eq 1 becomes:

$$\dot{\epsilon} = \text{constant}_1 \times T \times e^{-\frac{\Delta F}{RT}} \sinh \text{constant}_2 \left( \frac{\sigma - \bar{\sigma}_i}{RT} \right) \quad [2]$$

when  $\bar{\sigma}_i$  is the effective internal stress. For a series

Fig. 9—Effect of annealing on secondary creep rate at 50,000 psi and 1200°F of solution-treated low carbon N-155 bar stock reduced 15 pct at 80°F.

of tests at constant  $T$  and  $\sigma$ , but with varying  $\bar{\sigma}_i$ , eq 2 can be rewritten:

$$\log \dot{\epsilon} = \text{constant}_3 - \text{constant}_4 \times \bar{\sigma}_i \quad [3]$$

Assuming a linear relation between  $\bar{\sigma}_i$  and the line width as measured herein, this is the relationship appearing on Fig. 10.

There are difficulties, however, in selecting from line broadening data an average internal strain and in turn converting this to an average internal stress. What half-height width of a line represents in terms of some average internal stress is not known, without further analysis of the broadened lines and other assumptions.<sup>1</sup> Even the correction for instrumental broadening using Warren's method is dependent upon an assumption as to the shape of the broadened lines, which assumption imperfectly represents the facts in this case. One is forced therefore, to conclude that the quantitative theoretical significance of Fig. 10 is limited at the present time, although qualitatively it indicates the relationship between internal stress and creep resistance.

The point (3) for the material reduced 40 pct at room temperature fell far off the correlation of Fig. 10. The observed creep rate of this material was too high for the measured line width. Further, the data of Fig. 6 showed that the (220) line width of this material (and this material only) was reduced appreciably during annealing at 1200°F. The conclusion is that reductions of the order of 40 pct on low carbon N-155 in the cold-working range resulted in appreciable relaxation of internal stresses at temperatures as low as 1200°F, such relaxation occurring during the creep test at this temperature. This limits the amount of reduction, and internal stress formation, that is useful for service at 1200°F, as shown in Fig. 7. Further, the line width that should have been entered on the correlation of Fig. 10 was some average line width which existed during the creep test at 1200°F. All other samples for which the data lie on the correlation of Fig. 10 had structures stable enough at 1200°F after rolling and/or annealing that the line widths measured before testing were substantially those existing during the creep test at 1200°F.

The factors explained above, which limited the amount of cold reduction that was useful in improving creep resistance of low carbon N-155 at 1200°F to about 40 pct, can be generalized somewhat with the aid of data published by Zschokke.<sup>4</sup> Zschokke found on another austenitic steel that there was a maximum benefit from cold working similar in na-

Fig. 10—Correlation of creep rate at 50,000 psi and 1200°F with (220) width of solution-treated, "cold" worked and annealed low carbon N-155 alloy.

ture to the results shown in Fig. 7. There appears to exist therefore, a critical amount of cold work beyond which relaxation of the internal stresses will occur to such an extent at the temperature of test or service considered that a maximum value for internal stresses effectively exists at each such temperature. Further, Zschokke found that the amount of cold work which gave the maximum effect decreased with increasing creep test temperature. This may be explained by saying that the temperature at which relaxation occurs to any appreciable extent is reduced as the amount of cold working is increased.

The materials reduced 15 pct at either room temperature or 1400°F were similar in every respect in regards to the interrelation between line width or internal stress and creep resistance either before or after annealing. Further, the results shown on Fig. 4 indicate that internal stresses after reductions of 15 pct are also the same up to temperatures of reduction of the order of 1500°F. Beyond this point relaxation during the rolling operation occurs. Since it is the internal stresses which improve creep resistance, it can be said that the temperature of "cold work" is immaterial as far as creep resistance is concerned over the temperature range, 80° to 1500°F.

The data for material rolled at 2200°F and the as-solution-treated material also did not fall on the correlation of Fig. 10 (points 1 and 2). Further, Fig. 8 showed that within the temperature range 1800° to 2200°F a rather curious reversal in creep resistance occurred. In view of the above, it seems that the creep resistance for material rolled in the vicinity of 2200°F and the solution-treated material was abnormally high, if internal stress control as exemplified by Fig. 10 is considered normal. No fundamental explanation of this phenomenon appears possible at the present time. However, from a technological standpoint the finding is important since the conclusion is that rolling of solution-treated N-155 at temperatures in the vicinity of 2200°F resulted in material which had better creep resistance than other "hot" worked materials.

Key to Symbols Used in Fig. 10

## Conclusions

1—Cold working improves the creep resistance of low carbon N-155 and probably other alloys of the same general type through the presence of elastic stresses left in the lattice after the working operation.

2—For any given reduction, the optimum improvement in creep resistance can be had with any temperature of reduction below that which will allow relaxation of the internal stresses to a marked degree during the working operation itself. For reductions of 15 pct on low carbon N-155 alloy, this useful working temperature range is from 80° to 1500°F.

3—Conversely, increasing amounts of cold working give increasing creep resistance only up to the point where the internal stresses are so high as to permit relaxation to occur in significant amount at the particular service temperature being considered. It further appears that the critical amount of cold reduction decreases as the service temperature is raised. With low carbon N-155 for service or test at 1200°F, the critical cold reduction is approximately 25 pct.

4—A correlation of the logarithm of creep rate against internal stress as measured by diffraction line width existed for solution-treated and cold-rolled low carbon N-155 either with or without subsequent anneals. The full quantitative theoretical significance of this correlation must await more exact interpretation of broadened diffraction lines, although qualitatively it agrees with predictions from the Eyring reaction rate theory for creep.

# Thermal Variation of Young's Modulus in Some Fe-Ni-Mo Alloys

by M. E. Fine and W. C. Ellis

WHEN certain binary Fe-Ni alloys are worked cold and then stabilized by a stress-relief anneal, their Young's moduli are nearly invariant over a substantial temperature range determined by composition and work-anneal history.<sup>1</sup> In the present investigation addition of molybdenum to such alloys (besides increasing the yield strength) was found to diminish the sensitivity of the thermal coefficient of Young's modulus to composition changes. Such alloys are of interest for applications requiring a metal with controlled, low temperature coefficient of Young's modulus and substantial magnetic permeability.<sup>2</sup>

Young's modulus ordinarily decreases with rising temperature. In ferromagnetic alloys a change in modulus on heating due to loss of ferromagnetism modifies the temperature dependence. Far below the Curie temperature ferromagnetism alters the modulus in two ways: a—Addition of the energy of magnetization, a function of interatomic distance, changes the relation between interatomic energy and distance.<sup>1</sup> This lowers the modulus in the Fe-Ni and Fe-Ni-Mo alloys of this investigation. b—An applied stress changes the ferromagnetic domain arrangement so that linear magnetostriction contributes to the strain and further lowers the modulus.<sup>3</sup> Since in the alloys of this investigation both effects lower the modulus, loss of ferromagnetism on heating changes the slope of the modulus-temperature curve in a positive direction. With increasing temperature the slope of the modulus-temperature curve, due to progressive loss of ferromagnetism, becomes less negative, goes through zero (the modulus is minimum), becomes positive, and resumes its normal negative value above the Curie temperature.<sup>1</sup> The increase in modulus and decrease in curvature in the modulus-temperature curve occurring on work hardening have been attributed to a reduction in effect (b).<sup>1,3</sup> In the absence of ferromagnetism work hardening through introduction of residual strains would be expected to decrease the modulus.<sup>4</sup>

## Alloy Preparation—Test Methods

Four series of alloys having nominal molybdenum contents of 5, 7, 9, and 10 pct and containing 47 to 58 pct Fe (the analyzed compositions are given in Table I) were melted in air and cast as bars weighing from 2 to 6 lb. The charge consisted of electrolytic nickel, Armco iron, molybdenum (99+ pct) or ferromolybdenum (62 pct Mo), manganese, and aluminum as a deoxidizer. The bars were swaged cold to the desired diameters with intermediate anneals. Alloys in this composition range are reported<sup>5</sup> to be face-centered cubic and ferromagnetic at room temperature. The Curie temperatures<sup>5</sup> decrease with molybdenum. For example, keeping the Ni/Fe ratio at unity and increasing the molybdenum from 0 to 17 pct decreases the Curie tempera-

ture from approximately 500°C to room temperature. (The 17 pct Mo alloy requires quenching to retain a single phase.<sup>5</sup>)

Young's modulus at a series of temperatures from -50° to 100°C was determined by a dynamic method previously described.<sup>1,6</sup> In this method Young's modulus is calculated from the resonant frequency (in this case approximately 50,000 cycles per second) of a rod sample (approximately 2 in. long) vibrating longitudinally in the first mode. The densities of the samples at room temperature, Table I, were determined by the standard method of weighing in air and reweighing in redistilled bromobenzene. The linear coefficients of expansion, Table I, needed to calculate the sample length and density at the temperature of measurement, were obtained by observing the change in length (22° to 100°C) of an 8 in. gage distance with a two microscope cathetometer. The values of density and coefficient of expansion in the few samples checked are independent of treatment to the accuracy reported. This was assumed to be general for all the samples. The modulus values are accurate to  $\pm 0.05 \times 10^{11}$  dynes per sq cm. However, values of thermal change in modulus are accurate to  $\pm 0.005 \times 10^{11}$  dynes per sq cm.

## Young's Modulus

Values at 25°C: The modulus values of 0<sup>1</sup>, 5, and 10 pct Mo alloys at 25°C are plotted in Fig. 1 as functions of nickel. After working cold, the samples were either recrystallized at 950° to 1000°C or given a low temperature stabilizing anneal at 400°C. The 400°C anneal does not reduce the hardness nor cause recrystallization. Annealing at 400°C does

Fig. 1—Young's modulus in Fe-Ni-Mo alloys at 25°C.

Previous to annealing, the binary alloys were swaged cold 74 pct from an initial diameter of 0.390 in.; the ternary alloys, 41 pct from 0.260 in. In the 5 pct Mo series, the molybdenum contents varied from 5.2 to 5.3 pct; in the 10 pct series, from 9.8 to 10.8 pct.

\*Annealing temperature. All annealing times were 1 hr.

$$\frac{1}{\text{cm}^2} = 1.4504 \times 10^{-5} \text{ psi.}$$

Fig. 2—Effect of annealing temperature and cold reduction on Young's modulus of two 10 pct Mo alloys.

Upper curve—alloy was initially cold reduced 41 pct from 0.260 in. diam. Lower curve—alloy was cold reduced indicated percentage from 0.210 and annealed at 400°C for 1 hr before testing. Temperature of test, 25°C.

relieve residual strains to the extent that subsequent heating to 100°C provides insufficient thermal energy to promote further relaxation.

Young's modulus depends on both composition and the state of strain in the alloy. The addition of molybdenum progressively raises the modulus of alloys in corresponding states of strain. Molybdenum additions, furthermore, render the modulus less sensitive to change in nickel content. The theory of the effect of molybdenum on the modulus is discussed in a later section.

In all the alloys of Fig. 1, except 35.7 pct Ni-Fe,<sup>1</sup> the presence of work hardening increases Young's modulus as shown by comparison of the curves for the 400° and 1000°C anneals (due to a decrease in the stress-produced linear magnetostriction). The effect of cold reduction was studied in more detail in a 10.7 pct Mo, 40.1 pct Ni alloy, lower curve, Fig. 2. The modulus in this alloy increases almost uniformly with the amount of cold reduction. In the upper curve of Fig. 2 annealing temperature (9.9 pct Mo, 41.7 pct Ni alloy) is the variable; the initial cold reduction is kept constant. As the annealing temperature is increased the modulus at first increases, due to stress relief, and then de-

Fig. 4 (right)—Percentage thermal variation of Young's modulus in cold-worked and stress-relieved 7 and 9 pct Fe-Ni-Mo alloys.

Cold swaged from 0.300 to 0.200 in. diam. (56 pct). Annealed 1 hr at 500°C. An annealing temperature of 500°C was chosen instead of 400°C (Fig. 3b) because in the Fe-Ni-Mo alloys annealed 1 hr at 400°C the modulus increased slightly during a two week treatment at 150°C.

Fig. 6 (left)—Percentage thermal change in Young's modulus as affected by variation in degree of cold work and annealing temperature.

CR (cold reduced) refers to reduction in cross-sectional area.

Fig. 7 (left)—Permeabilities of some Fe-Ni-Mo alloys.

● — Cold reduced 41 pct from 0.260 in. diam and annealed 1 hr at 400°C.  
 Δ — Cold reduced 56 pct from 0.300 in. diam and annealed 1 hr at 500°C.  
 The permeabilities of the 8.8 pct Mo alloy are higher than the 5.3 and 10.7 pct Mo alloys because the former was annealed at a higher temperature.

Fig. 8 (right)—Effect of increasing molybdenum on the modulus-temperature curve.

Upper curves—work hardened condition. Lower curves—fully annealed condition. Arrows indicate minima in modulus-temperature curves.

of the Curie temperature, a function of composition. Consistent with the dependence of the Curie temperature on nickel and molybdenum, the temperature of minimum modulus (predicted from the observed slopes in the  $-50^{\circ}$  to  $100^{\circ}\text{C}$  range) increases with nickel content and decreases with molybdenum content. The effects of molybdenum and nickel are interrelated; for a minimum modulus at room temperature the ratio of nickel to iron increases from 0.7 to 0.9 as the molybdenum is increased from 0 to 10 pct.

The curvature in the modulus change-temperature curves (Fig. 3a) about the temperature of minimum modulus decreases on adding molybdenum. (Compare the data for the 0, 5, and 10 pct Mo alloys whose minima are in the temperature range of test). Furthermore, the slopes at temperatures considerably removed from the minimum modulus become numerically less as molybdenum is added.

Cold working of binary Fe-Ni alloys causes the modulus change-temperature curves to be shallower at their minima.<sup>1</sup> Moreover, the slope changes much more gradually at temperatures considerably removed from the minimum. In cold-worked alloys, the presence of the molybdenum to some extent further reduces the curvature in the region of the minimum, but its principal effect is to decrease the sensitivity of the temperature coefficient of modulus to change in nickel content. The evidence for this is in the modulus change-temperature curves for the cold-worked condition (stabilized by a stress-relief anneal at  $400^{\circ}$  or  $500^{\circ}\text{C}$ ) shown in Figs. 3b and 4; the curves fan out less from varying nickel as the molybdenum content is increased. The same effect is illustrated more directly in Fig. 5, showing the mean thermal coefficient of modulus in 0, 5, 7, 9, and 10 pct Mo alloys between  $-50^{\circ}$  and  $100^{\circ}\text{C}$  (slopes of the curves in Fig. 3b and 4). The major effect is for molybdenum contents of more than 5 pct. Adding 9 or 10 pct Mo diminishes the sensitivity of the coefficient to variations in Fe-Ni ratio by a factor of two.

Adding nickel increases the temperature of minimum modulus in both cold-worked and fully annealed alloys. The effect of molybdenum is not so simple. Adding molybdenum to fully annealed alloys decreases the temperature of minimum, but in cold-worked alloys adding molybdenum increases the temperature of minimum modulus. The temperature of minimum in cold-worked binary Fe-Ni

alloys is less than in fully annealed alloys. As molybdenum is added the temperatures of minimum for the two conditions approach each other, are equal at approximately 7 pct Mo, and in 10 pct Mo alloys the temperature of minimum is higher for the cold-worked condition (compare Fig. 3a and 3b). This observation has theoretical significance and will be discussed later in the paper.

The effects of cold working were investigated in more detail in two alloys. The results are shown in Fig. 6a and 6b. The samples were first fully annealed at  $1000^{\circ}\text{C}$  and then cold worked the percentages shown in the figure (followed by a stabilizing anneal at  $400^{\circ}\text{C}$ ). The initial amounts of cold work produce the greatest effect in flattening and shifting the minimum. This suggests that the principal changes effected by cold work are not due to texture development, since such small amounts of cold work would hardly be expected to develop preferred orientations. These figures again show the opposite effect of the presence of cold work in shifting the minimum in the 5 and 10 pct Mo alloys. The initial cold reduction decreases the temperature of minimum in the former, Fig. 6a, but increases the temperature of minimum in the latter, Fig. 6b. Subsequent cold reduction in both cases decreases the thermal coefficient of modulus.

The effect of change in annealing temperature on the modulus-temperature relation in a 10 pct Mo alloy was studied in detail, Fig. 6c. Increasing the annealing temperature from  $400^{\circ}$  to  $1000^{\circ}\text{C}$  decreases the temperature of minimum from well above  $100^{\circ}\text{C}$  to approximately  $0^{\circ}\text{C}$ ; the slope becomes more positive. Comparing the curves for the  $800^{\circ}$  and  $1000^{\circ}\text{C}$  anneals at their minima, the latter has more curvature.

The effects of cold work and annealing temperature on the temperature of minimum modulus (Fig. 6b and 6c) are mutually consistent. The largest effect of cold work occurs for small cold reductions; the largest effect of annealing is for removal of the last residual strains introduced by the working ( $800^{\circ}$  to  $1000^{\circ}\text{C}$ ). Decrease in temperature of anneal (less removal of strain) has the same effect as increase in strain by cold work.

When the final annealing temperature is constant, the modulus and the thermal variation in modulus depend principally upon the amount of cold reduction after the last full anneal; however, the modulus and thermal variation in modulus depend to some

extent on the working and annealing procedure before the last full anneal. This is not unusual for a property depending upon the state of internal strain.

### Magnetic Permeability and Mechanical Strength

Properties of associated importance with the modulus characteristics are the magnetic permeability and the strength. Permeabilities for some alloys are shown in Fig. 7. The thermal permeability variation (at 3500 gauss) is principally due to the decrease in Curie temperature as molybdenum is added. In a 10.7 pct Mo, 38.4 pct Ni alloy cold worked and stress relieved at 400°C, the permeability falls to a low value at 85°C indicating the Curie temperature is not much higher. The permeability of an 8.8 pct Mo, 40.6 pct Ni alloy stress relieved at 500°C remains between 700 and 900 for the temperature variation, -40° to +85°C. The permeabilities are higher in this latter alloy because the annealing temperature is higher.

The strengths of Fe-Ni alloys are substantially increased by addition of molybdenum. For example, an alloy containing 8.9 pct Mo and 41.6 pct Ni, cold worked 56 pct and stress-relief annealed at 500°C has a proportional limit of 115,000 psi. An Fe-Ni alloy containing 45 pct Ni after similar treatment has a proportional limit of 50,000 psi. The ultimate tensile strength of the molybdenum containing alloy is 148,000 psi and the elongation in 2 in. is 2 pct.

### Theory of Effect of Mo on the Modulus

Addition of molybdenum to Fe-Ni alloys modifies the modulus through its effects on ferromagnetism and interatomic binding energy. Ferromagnetism, responsible for the observed unusual temperature variation of modulus in Fe-Ni and Fe-Ni-Mo alloys, as previously stated, changes the modulus directly through addition of the energy of magnetization term to the interatomic binding energy. Furthermore, the stress-produced linear magnetostriction increases the strain and lowers the modulus. In the following discussion the former will be referred to as effect (a) and the latter effect (b).

The modulus as it varies with temperature in a 0, 5, and 10 pct Mo alloy (approximately 42 pct Ni) is shown schematically in Fig. 8. The upper curve of each set is for work-hardened alloys, the lower for well-annealed alloys. In the temperature range -50° to 100°C these curves were constructed from actual data. The approximate behavior over a considerably wider temperature range can be deduced from room temperature measurements, since reducing the nickel lowers the Curie temperature and is approximately equivalent to lowering the temperature of test. The curves for the two alloy conditions are shown coming together at the Curie temperature. Actually this may not happen due to the effects of internal strain and crystal orientation on the modulus. To a first approximation the lowering of the upper curve from a straight line extrapolated from above the Curie temperature is due to effect (a); the difference between upper and lower curves is due to effect (b).

Addition of molybdenum, which increases the mechanical strength, by obstructing domain movement reduces the stress-produced linear magnetostriction (b). This partially causes the increase in modulus and decrease in curvature in the modulus-temperature curve on adding molybdenum to well-annealed alloys (Figs. 1 to 3 and 8). Effect (b) increases in magnitude, Fig. 8, over a limited temperature range on heating as in nickel<sup>7</sup> probably because

domain movement becomes easier as the temperature is raised.

Effect (a), as molybdenum is increased, diminishes in magnitude and the minimum due to it nears the Curie temperature. Hence, in 0 and 5 pct Mo alloys work hardening, that is, reducing effect (b), decreases the temperature of minimum in the modulus-temperature curve, but in 10 pct Mo alloys work hardening increases the temperature of minimum as shown by the arrows in Fig. 8. Confirming experimental evidence for a diminishing of effect (a) on adding molybdenum comes from expansion data: The coefficient of expansion increases on adding molybdenum, Table I, showing a decrease in the volume effect from loss of ferromagnetism. The decrease in volume effect implies that as molybdenum is added the interatomic distance corresponding to maximum energy of magnetization nears the nonferromagnetic interatomic distance.

### Summary

Young's modulus and its temperature coefficient were investigated in low coefficient Fe-Ni-Mo alloys under varying conditions of working and annealing. In the ternary as well as the binary Fe-Ni alloys, the temperature interval of nearly constant Young's modulus is greatly extended by work hardening. A stress-relief anneal is necessary to stabilize the alloys. Addition of 9 or 10 pct Mo decreases the sensitivity of the thermal coefficient to variations in nickel by approximately a factor of two. In these alloys the mean thermal coefficient of modulus for the temperature range -50° to 100°C varies from +50 to  $-50 \times 10^{-6}$  degree C<sup>-1</sup> as the nickel varies from 36.5 to 41.5 pct.

An alloy containing 9 pct Mo, 38 to 41.5 pct Ni, and balance Fe in the cold-worked condition has a low temperature coefficient of Young's modulus, substantial magnetic permeability reasonably constant over a limited temperature range, and high strength. The coefficient of modulus can be controlled by controlling the Fe-Ni ratio. A further measure of control can be exercised by varying the straining-annealing procedure.

The principal effects of molybdenum on the temperature dependence of modulus are explained by assuming that molybdenum decreases the modification in the interatomic energy-interatomic distance relation from the energy of magnetization.

### Acknowledgments

The authors are pleased to express appreciation for the valuable assistance of members of the Bell Telephone Laboratories. The alloys were prepared under the direction of D. H. Wenny; the analyses and densities were supplied by H. E. Johnson; C. W. Spencer obtained the expansion data; the magnetic measurements were furnished by V. E. Legg and the mechanical properties by I. V. Williams. E. E. Schumacher assisted greatly through his interest, encouragement, and counsel.

# Effect of Rate of Cooling on the Alpha-Beta Transformation in Titanium and Titanium-Molybdenum Alloys

by Pol Duwez

The effect of the rate of cooling on titanium, zirconium, and thallium has been measured. For titanium-molybdenum alloys, it has been shown that for molybdenum concentration up to 8 pct the rate of cooling has no effect on the transformation temperature, but this temperature decreases progressively with increasing molybdenum content.

HIGH-strength to weight ratio and remarkable corrosion resistance have often been advanced as the main reasons for the present widespread interest in titanium. For the physical metallurgist, the existence of an allotropic transformation in titanium is another important factor. As in the case of iron, an allotropic transformation may be the fundamental property upon which the response of Ti-base alloys to heat treatment will depend. It is therefore important to study the mechanism of the allotropic transformation in pure titanium and the effect of alloying elements on this transformation.

The existence of an allotropic transformation in titanium was reported in 1931 by Schulze.<sup>1</sup> Later, De Boer et al.<sup>2</sup> determined the transformation temperature from a discontinuity in the electrical resistivity at  $882^{\circ}\pm 20^{\circ}\text{C}$ . According to recent work,<sup>3</sup> the transformation temperature is  $882.5^{\circ}\pm 1^{\circ}\text{C}$ . The crystal structure of the room temperature  $\alpha$  phase is hexagonal close-packed and the high temperature  $\beta$  phase is body-centered cubic.<sup>4</sup>

It is well known that the high temperature  $\beta$  phase of pure titanium cannot be retained by quenching to room temperature. Several investigators<sup>5-7</sup> have shown that in alloys of titanium with metals which are soluble in the  $\beta$  phase (for example, nickel, molybdenum, chromium, or manganese), the  $\beta$  structure can be retained, providing the concentration of the alloying element is greater than a certain critical value. Below this critical value, the alloys transform during quenching, at least partially, into a supersaturated solid solution having the  $\alpha$  structure. This behavior is very similar to that

found in some iron binary alloys (Fe-Ni and Fe-Mn, for example) and is an indication that the transformation might occur by means of a shear mechanism analogous to that observed in the austenite-martensite reaction.

The present investigation is mostly concerned with the effect of the rate of cooling on the  $\beta$  to  $\alpha$  transformation. In the first portion of this paper, the results obtained on pure titanium are described. Two other pure metals, zirconium and thallium, were also investigated, because they both have an allotropic transformation like titanium, from an hexagonal close-packed to a body-centered cubic structure. For purposes of comparison, the effect of rate of cooling of the  $\gamma$  to  $\alpha$  transformation of iron was included in the experimental program. The second part of this paper deals with Ti-Mo alloys. The equilibrium phase boundaries involving the solid state reactions on the Ti-rich side of the system were determined and a study was made of the effect of the rate of cooling on the transformation of the high temperature  $\beta$  solid solution.

## Experimental Procedure

Since the main object of the present investigation was the determination of the effect of the rate of cooling on a transformation temperature, the best technique available was that used by Greninger<sup>8</sup> in his study of the martensite arrest in carbon steels. This method consists of heating a very small sample of metal to which fine thermocouple wires are attached, cooling the sample rapidly by means of a blast of helium, and recording the temperature vs. time curve on an oscillograph. The apparatus used in the present experiments was very similar to that described by Greninger, except that the heating coil was made of molybdenum wire (0.040 in. in diam) and the assembly was placed in a bell jar under vacuum of  $10^{-5}$  mm Hg or less. The specimen con-

P. DUWEZ, Member AIME, is Associate Professor of Mechanical Engineering, California Institute of Technology, Pasadena, Calif.

Discussion on this paper, TP 3124E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 12, 1951. Detroit Meeting, October 1951.

Fig. 1—Cooling curves obtained on pure titanium at various rates of cooling.

sisted of two pieces of metal about 0.020 in. thick and less than 1/16 in. square. The 0.005 in. chromel-alumel thermocouple wires were placed between the two pieces of metal and the assembly spot welded. In an effort to reduce contamination of titanium by any residual oxygen and nitrogen, the specimen was heated as fast as possible (between 5 and 10 sec) above the transformation temperature and immediately quenched. The temperature was recorded on a rotating drum type oscillograph (made by the William Miller Corp., Pasadena, Calif.). The galvanometer was a 65 cycle element, having a resistance of 45 ohms and a sensitivity of 1 in. deflection per 25 microamperes. The instrument was calibrated by means of a Leeds and Northrup portable precision potentiometer. Records were obtained with paper speeds of about 4½ and 8 in. per sec.

The Ti-Mo alloys were prepared by melting in a helium arc furnace. The furnace was very similar to that described in ref. 9, except that the top electrode, made of molybdenum, was water cooled. This electrode was designed so that the cooling water was brought to the tip of the electrode, leaving only 3/16 in. of molybdenum between the arc and the cooling water. The operation of the furnace was frequently checked by melting a specimen of pure titanium and measuring the Vickers hardness before and after melting. It was assumed that no contamination was introduced by melting when the average Vickers hardness number did not increase by more than 5 points.

The melting procedure consisted of loading the desired amount of molybdenum powder into a cavity drilled in a piece of titanium and covering the cavity with a titanium cap. The total weight of a specimen was between 5 and 15 g. Each specimen was melted several times in order to obtain an homogeneous alloy. The alloys were not chemically analyzed after melting. Several specimens, however, were weighed before and after melting and, since the change in weight was found to be less than 0.2 pct, it was assumed that the change in composition, if any, was negligible. After melting, the alloys that were sufficiently ductile (up to about 10 pct Mo) were cold rolled with various reductions in cross-

section. All the specimens, whether rolled or not, were sealed in evacuated fused silica tubes (vacuum of  $10^{-4}$  mm Hg or less) and homogenized for 24 hr at 982°C (1800°F). The specimens were then quenched in water from that temperature. All subsequent heat treatments were also carried on in evacuated fused silica capsules. All these heat treatments were made at constant temperature and followed by quenching.

For microscopic observation, the specimens were polished by conventional methods, finishing with 0 to 2 microns diamond powder and etching with a solution of one part 48 pct hydrofluoric acid, one part concentrated nitric acid, and two parts glycerine. A magnification of 250 times was used.

## Results of Measurements on Pure Metals

**Titanium:** Pure titanium obtained by the iodide process was received from the Foote Mineral Co. and from the New Jersey Zinc Co. A small piece of iodide titanium was also obtained from the Naval Research Laboratory through the courtesy of Dr. Chapin. The Vickers hardness (10 kg load) of any of these three specimens varied from about 55 to 75, this variation within a given sample being due probably to crystal orientation. Measurements of Vickers hardness therefore was not suitable for detecting possible differences in the degree of purity of the three samples.

A total of approximately 170 cooling curves was obtained with various rates of cooling ranging from 4° to about 15,000°C per sec. Typical cooling curves obtained with various rates of cooling are shown in Fig. 1. With the exception of a few tests, the break in the cooling curve at the transformation point was quite easy to locate and the accuracy of measurement of the transformation temperature was approximately  $\pm 4^\circ\text{C}$ .

The results of measurements on the three samples of iodide titanium are summarized in the graphs of Fig. 2. The scatter between transformation temperatures measured on several samples around a given rate of cooling seems to exceed  $\pm 4^\circ\text{C}$ , which is the estimated accuracy of measurement. It is probable that part of the scatter is due to the statistical nature of the nucleation process. In any case, all the measurements seem to be included in a band which has a width of about  $10^\circ\text{C}$  at low rates of cooling and of about  $20^\circ\text{C}$  at high rates. By taking the center line of such a band as an average curve, it may be concluded that the  $\beta$  to  $\alpha$  transformation of titanium decreases slightly with increasing rates of cooling and varies from 882°C at relatively low rates to about 850°C at cooling rates of the order of 10,000°C per sec.

In about half of the 170 cooling curves obtained for the pure titanium specimens, a more or less pronounced heat effect was observed at a temperature higher than that at which the main thermal arrest took place. In many cases a definite change in the slope of the cooling curve was noticeable, as shown at point X on one of the graphs reproduced in Fig. 1. The temperature at which this anomaly was observed varied from specimen to specimen, covering a range from 905° to about 960°C. The variation in the temperature at which the extra thermal arrest was observed excluded the possibility of a second allotropic transformation, although such a transformation has been suggested by McQuillan.<sup>10</sup>

In a more detailed investigation recently published,<sup>8</sup> this same author seems to refute his previous

conclusions and demonstrates that the anomalies observed in the behavior of titanium around the  $\alpha$ - $\beta$  transformation are due to contamination of the specimens by oxygen. In measuring the equilibrium pressure of hydrogen in contact with a titanium specimen as a function of temperature, McQuillan found that, on heating, the discontinuity in pressure is very sharp at the  $\alpha$ - $\beta$  transformation temperature (882.5°C). As the temperature is increased, however, the specimen seems to continue transforming up to (in one case) about 930°C and from there on the pressure-temperature relationship becomes normal (linear relation between  $\log p$  and  $1/T$ ). The explanation for the progressive transformation is that even in a vacuum as low as  $10^{-5}$  mm Hg, there is enough residual oxygen to contaminate the outside layer of the titanium specimen. It is therefore logical to expect that the uncontaminated part of the specimens (the inside core) will transform at 882.5°C with a sharp discontinuity in the pressure. The outside layer, which contains all concentrations of oxygen from zero to a maximum at the surface, will transform gradually over a range of temperatures corresponding to the range of oxygen concentration present. Upon cooling, the reverse mechanism takes place, and the same relationship is observed between the pressure and temperature. By introducing a very small amount of oxygen into the vacuum chamber in order to purposely contaminate the specimen, McQuillan observed that the range of temperature over which the transformation proceeds was increased, and in one case extended from 882.5° to about 960°C.

The conclusions reached by McQuillan concerning the effect of surface contamination on the transformation temperature of titanium clearly explain the anomalies found in the cooling curves discussed in the present study. The very thin specimen used in the quenching experiments is, of course, subject to some contamination by residual oxygen and nitrogen, even if, as stated above, the time necessary for heating the specimen is of the order of seconds only. The oxygen contaminated case around the specimen undergoes the  $\beta$  to  $\alpha$  transformation at temperatures above the normal transformation temperature and a decrease in the slope of the cooling curve is observed as shown at point X of Fig. 1. When the transformation temperature of pure titanium is reached, the uncontaminated core of the specimen transforms and the main thermal arrest appears on the cooling curve. Since the degree of contamination is not exactly the same from test to test, the first break in the cooling curve is sometimes more or less pronounced and sometimes absent. When the extra thermal arrest is actually observed, it is not always at the same temperature, but always within a range which is very nearly the same as that found by McQuillan (905° to 960°C).

Table I. Effect of Rate of Cooling on Transformation Temperature of Thallium

| Rate of Cooling,<br>°C per Sec | Transformation<br>Temperature, °C |
|--------------------------------|-----------------------------------|
| 105                            | 231                               |
| 650                            | 228                               |
| 950                            | 233                               |
| 1120                           | 229                               |
| 1500                           | 231                               |
| 2150                           | 229                               |
| 3000                           | 232                               |
| 8100                           | 230                               |

Fig. 2—Effect of rate of cooling on the allotropic transformation temperature of titanium (iodide process). Upper graph: Foote Mineral Co. titanium. Lower graph: ○—New Jersey Zinc Co. titanium. ●—Naval Research Laboratory titanium.

**Zirconium:** Because zirconium and titanium have very similar physical properties, it was anticipated that the effect of the rate of cooling on the  $\beta$  to  $\alpha$  transformation of zirconium would be the same as that found for titanium. About 85 cooling curves were recorded on zirconium specimens cut from a bar of pure zirconium made by the iodide process by the Foote Mineral Co. The results, shown in Fig. 3, indicate that the transformation temperature of zirconium decreases from 865° to about 850°C with increasing rates of cooling. The effect of rate of cooling is therefore smaller for zirconium (about 15°C) than for titanium (about 35°C).

It is interesting to mention that for zirconium no additional thermal arrest of the type found for titanium was observed on any of the cooling curves. Since the experimental conditions were the same for the two metals, it seems that either the rate of absorption of oxygen and nitrogen is smaller in zirconium than in titanium, or that the transformation temperature of zirconium is not greatly affected by oxygen and nitrogen. Since zirconium is generally considered as a better “getter” than titanium, the second hypothesis is probably the more likely one.

**Thallium:** Besides titanium and zirconium, thallium is the only other element having an allotropic transformation from a high temperature, body-centered cubic form to a low temperature, hexagonal close-packed form.<sup>11\*</sup> A few measurements were performed on 99.9 pct pure thallium obtained from Belmont Smelting & Refining Works, Brooklyn. The thermal arrest was not as pronounced as in the case of titanium and zirconium, due to the fact that the latent heat of transformation for thallium is only 0.074 kcal per mol compared with 0.71 for zirconium.<sup>12</sup> However, the arrest could be located easily and the accuracy in the temperature measurement was about  $\pm 4^\circ\text{C}$ . The results summarized in Table I indicate that up to a rate of cooling of about 8000°C per sec, the transformation temperature remains within the limits of accuracy of  $\pm 4^\circ\text{C}$ . It may be concluded therefore that if rates of cooling up to 8000°C per sec have any effect on the transformation temperature of thallium, this effect is less than about  $\pm 4^\circ\text{C}$ .

**Iron:** Although many studies have been published on the effect of the rate of cooling on the transformation in Fe-base binary alloys, the early results of Esser et al.<sup>13</sup> seem to be the only ones obtained on relatively pure iron and with high rates of cooling. According to these investigators, the  $\alpha$  to  $\gamma$  transformation can be depressed from 905°C to as low as about 500°C at cooling rates of the order of 10,000°C per sec. The only information on the carbon content of the material used by Esser is that it was less than 0.017 pct and no definite statement is made concern-

\* Since this work was completed, a body-centered cubic to hexagonal close-packed allotropic transformation has been found in hafnium; it will be described in a forthcoming paper.

○—Bureau of Standards iron. ●—National Research Corp. iron.  
Fig. 3—Effect of rate of cooling on the allotropic transformation temperature of zirconium (upper) and iron (lower).

ing other possible impurities. Since Esser's experiments were performed in an atmosphere of hydrogen, there might also be some question about the effect of hydrogen absorption on the allotropic transformation.

Since iron may be obtained at present with a higher degree of purity than at the time the work of Esser was reported, 1933, the effect of rate of cooling on the  $\gamma$  to  $\alpha$  transformation temperature was reinvestigated on two different iron samples. The first sample was a small bar of spectroscopically pure iron from the Bureau of Standards. The purity of this particular sample (ingot No. 8) has been described in ref. 14; the carbon content is less than 0.001 pct. The second kind of iron was a 10 lb vacuum-cast ingot purchased from National Research Corp., Boston, Mass. A typical analysis of this type of metal is less than 0.005 pct C, less than 0.02 pct O, less than 0.001 pct N and H, and traces of various metallic impurities (each less than 0.001 pct).

The effect of the rate of cooling on the  $\gamma$  to  $\alpha$  transformation is shown in Fig. 3 for the two types of iron tested. In approximately half of the cooling curves, a more or less pronounced recalescence took place at the transformation temperature. This behavior is indicated on the diagram of Fig. 3 by means of a vertical line connecting the minimum temperature corresponding to the beginning of transformation to the maximum temperature reached after recalescence. In spite of the relatively large scatter in experimental results, Fig. 3 indicates clearly that

Fig. 4—Partial phase diagram of the Ti-Mo system. Curve M indicates the transformation temperature during quenching from the beta field.

by increasing the rate of cooling it is possible to decrease the allotropic transformation temperature of iron from 905°C to approximately 750°C at a cooling rate of about 10,000°C per sec. This decrease of the  $\gamma$ - $\alpha$  transformation temperature is much smaller than that reported previously by Esser et al.<sup>13</sup> The most probable reasons for the lack of agreement between the two investigations are, first, the difference in the purity of the iron samples, and second, the effect of hydrogen used as an atmosphere in Esser's experiments.

In any case, the rate of cooling has a greater influence on the  $\gamma$  to  $\alpha$  transformation temperature of iron than on the  $\beta$  to  $\alpha$  transformation temperature of titanium, zirconium, and thallium. In addition, recalescence was frequently observed in iron, but never occurred in any of the measurements made on the other three metals.

Results of thermal analysis measurements are difficult to interpret on a quantitative basis and therefore it is not possible to determine exactly the

10.85 pct Mo ( $\alpha'$ ). 12.7 pct Mo ( $\beta$ ).  
Fig. 5—Structure of Ti-Mo alloys quenched from 980°C.

factors responsible for the differences between the behavior of titanium and that of iron. The change in crystal structure is of course a factor to consider. From this point of view, the results indicate that the rate of cooling has less effect on a body-centered cubic to hexagonal close-packed transformation than on a face-centered cubic to body-centered cubic transformation. This observation, however, does not lead to the conclusion that the atomic processes involved in titanium and in iron are necessarily different. In fact, both transformations are probably of the nucleation and shear type, and apparent lack of similarity in the behaviors of the two metals during fast cooling may simply be the result of differences in the numerical values of the basic factors controlling the rate of nucleation and the energy involved in the shearing process. Further work in the field of phase transformation in pure metals is obviously necessary to answer these questions.

#### Titanium-Molybdenum System

On the basis of the Hume-Rothery rules governing the formation of solid solutions, titanium and molybdenum should be completely soluble in each other at high temperature. Previous work on this system<sup>8</sup> and additional unpublished results obtained in this laboratory have confirmed this prediction. At temperatures below the  $\alpha$ - $\beta$  transformation of titanium, the solubility of molybdenum in  $\alpha$  titanium is apparently very small and the preliminary results<sup>8</sup> indicate that the Ti-Mo phase diagram below 882°C may be similar to the Fe-Ni diagram.

The results of the present study will be described in two parts, the equilibrium phase boundaries be-

71 pct Mo quenched from  
871°C ( $\alpha + \alpha'$ ).

4.35 pct Mo quenched from  
816°C ( $\alpha + \beta$ ).

10.85 pct Mo quenched from 816°C ( $\alpha + \beta$ ).

Fig. 6—Structure of Ti-Mo alloys quenched from 871° and 816°C.

tween 650° and 882°C and the effect of rate of cooling on the  $\beta$  to  $\alpha$  transformation in alloys containing less than 12 pct Mo.

**Equilibrium Boundaries Between 650° and 882°C:** A series of Ti-Mo alloys containing up to about 20 pct Mo were prepared by the arc-melting method described above. All the alloys were first heated to 980°C for 24 hr and quenched in water. Subsequently they were held at constant temperature for 5 days at 871°C and at 816°C, 10 days at 760°C, 20 days at 700°C, and 30 days at 650°C. The alloy compositions and the structures observed after heat treatment are shown by symbols on Fig. 4.

After quenching from 980°C, the alloys containing 2.3, 3.2, 4.35, 5.6, and 10.85 pct Mo had the typical Widmanstätten microstructure (cf. Fig. 5) found in titanium alloys in which the high temperature  $\beta$  solid solution is transformed, at least partially, into the supersaturated  $\alpha$  solid solution. For simplicity, this supersaturated solid solution will be called  $\alpha'$ , following the nomenclature used by Troiano and McGuire<sup>16</sup> in their study of the Fe-Mn system. The alloy containing 12.7 pct Mo, after quenching, had the  $\beta$ -retained structure (cf. Fig. 5). Hence, the minimum amount of molybdenum necessary to retain the  $\beta$  structure after quenching is around 12 pct Mo.

X-ray diffraction patterns were also taken of the alloys quenched from 980°C. In order to obtain the sharpest possible patterns, the powder was first filed from the quenched specimens, sealed in evacuated quartz tubes, reheated rapidly to 980°C for 5 min, and then quenched in liquid argon.<sup>†</sup> In spite of these precautions, the patterns were not sharp enough to show resolved doublets in the back-reflection range. This lack of resolution is probably

due to the strain introduced by the alloying element in a supersaturated  $\alpha$  titanium lattice.

In spite of their lack of sharpness, the X-ray diffraction patterns indicated quite clearly that, in addition to the  $\alpha'$  phase, the  $\beta$  phase was also present in alloys containing 4.35, 5.6, 9.35, and 10.85 pct Mo. Judging from the relative intensity of the  $\alpha'$  and the  $\beta$  patterns, it was also clear that the amount of the  $\beta$  phase was increasing with molybdenum content. This behavior is very similar to the well-known phenomenon of retained austenite in steels. A quantitative study of the relative amount of  $\alpha'$  and retained  $\beta$  could probably be made by using the special X-ray diffraction methods successfully applied by Averbach and Cohen<sup>17</sup> for determining the amount of retained austenite.

The structure of the alloys was investigated by microscopy after attaining equilibrium at 871°C and below. After the 871°C treatment, alloys with 4.35 and 7.1 pct Mo contained  $\alpha$  in a matrix of  $\alpha'$ , the latter formed by the transformation of  $\beta$  during cooling, as shown in Fig. 6. The alloy containing 10.85 pct Mo was  $\alpha'$  and the alloys containing 12.7 and 14.3 pct Mo had the  $\beta$ -retained structure. These results, shown by symbols on the diagram of Fig. 4, indicate that at 871°C the phase boundary between the  $\alpha + \beta$  and the  $\beta$  fields must cross the 871°C line between 7.1 and 10.87 pct Mo. This location of the phase boundary is compatible with the fact that in the alloys containing 4.35 and 7.1 pct Mo the  $\beta$  phase was not retained after quenching. In these alloys the  $\beta$  phase contains less than the critical value of 12 pct Mo and consequently transforms into  $\alpha'$  dur-

<sup>†</sup> As is explained in ref. 16, titanium powder reacts with water during quenching and a change in lattice parameter of  $\alpha$  titanium, probably due to absorption of oxygen, has been observed.

1.8 pct Mo ( $\alpha + \beta$ ).

10.85 pct Mo ( $\alpha + \beta$ ).

12.7 pct Mo ( $\alpha + \beta$ ).

14.3 pct Mo ( $\alpha + \beta$ ).

Fig. 7—Structure of Ti-Mo alloys quenched from 760°C.

Fig. 8—Effect of the rate of cooling on the transformation temperature of Ti-Mo beta solid solution for various molybdenum concentrations.

ing quenching. The  $\alpha'$  structure in the alloy containing 10.85 pct Mo after the 871°C treatment is also logical, since this alloy was in the  $\beta$  field at temperature, but does not contain enough molybdenum to retain the  $\beta$  structure.

After the heat treatments at 816°, 760°, 700°, and 650°C, all the alloys contained either the two phases,  $\alpha$  and  $\beta$ , or the  $\beta$  phase only. These results are shown by appropriate symbols in the phase diagram of Fig. 4. Typical microstructures of some of the alloys are shown in Figs. 6 and 7. From these results, the phase boundary between the  $\alpha+\beta$  and the  $\beta$  fields may be traced as indicated in Fig. 4. It is, of course, impossible to describe the accuracy in the location of this phase boundary by means of numbers referring to either temperature or concentration. A good estimate of the accuracy can be gained by drawing the boundaries that would be shifted most towards low and high concentration and would still separate the two phase from the one phase alloy. It is believed that these two curves would not be further apart than 1 pct Mo, at the most.

No attempt was made to determine the boundary between the  $\alpha$  and the  $\alpha+\beta$  phases. The solubility of molybdenum in  $\alpha$  titanium, however, is probably very small. The alloy containing 0.8 pct Mo was found to be in a two-phase region at 700°C. A few X-ray diffraction patterns were made from other alloys containing less than 1 pct Mo and no appreciable shift in the powder pattern could be detected. It seems therefore that the solubility of molybdenum in  $\alpha$  titanium is less than 1 pct and high accuracy X-ray diffraction measurements will be necessary to establish the solubility limits.

The study of the phase diagram was not pursued at temperatures below 650°C because of the sluggishness of the reactions. It was found, for example,

that at 625°C equilibrium structures were not obtained after six weeks at temperature. The knowledge of the phase boundaries below 650°C, however, is not necessary for interpreting the results of the experiments made with high rates of cooling.

**Phase Transformation at High Rates of Cooling:** Since the alloys containing less than about 12 pct Mo transform from  $\beta$  to  $\alpha'$  during quenching, it was anticipated that the temperature at which this transformation takes place could be detected by thermal analysis. Alloys containing 2.3, 4.35, 5.75, 7.1, 8.15, 9.35, and 12.7 pct Mo were tested and temperature vs. time curves were recorded at various rates of cooling. For the alloys containing 2.3, 4.35, 5.75, and 7.1 pct Mo, a clearly defined thermal arrest was observed. Within the limits of experimental errors, the rate of cooling had no effect on the temperature at which the thermal arrest occurred (cf. Fig. 8). It is therefore established that Ti-Mo alloys containing 0 to 7.1 pct Mo transform from a  $\beta$  solid solution to a supersaturated  $\alpha$  solid solution at a temperature which is independent of the rate of cooling. This temperature decreases with increasing molybdenum content following a smooth curve, as shown in Fig. 4 (curve M).

The thermal analysis experiments made on the alloys containing 8.15, 9.35, and 12.7 pct Mo failed to reveal a thermal arrest. This is not surprising for the alloy containing 12.7 pct Mo, since in this alloy the  $\beta$  structure is retained after quenching. In the alloys containing 8.15 and 9.35 pct Mo, the results of microscopy and X-ray diffraction described in a previous section indicated that at least some of the high temperature  $\beta$  phase was transformed into supersaturated  $\alpha$  during quenching. For these alloys, the failure in measuring a heat effect by thermal analysis may be due to the fact that only a relatively small portion of  $\beta$  is undergoing the transformation and the method of measurement is not sufficiently sensitive to record a heat effect. In any case, it seems logical to assume that the partial transformation from  $\beta$  to  $\alpha'$  in the range of concentration from about 8 to about 11 pct Mo takes place at temperatures below 500°C and the transformation temperature vs. concentration curve in this range is probably an extension of the curve measured for lower concentrations. It is interesting to point out that by extrapolating the solid curve M of Fig. 4 to higher concentrations (as shown by the dotted portion of the curve), it appears that the transformation temperature would be below room temperature when the molybdenum concentration is about 12 pct. This is the approximate concentration above which the  $\beta$  phase is actually retained after quenching from high temperature.

### Allotropic Transformation in Titanium Alloys

The striking analogy between the Ti-Mo alloys and some of the Fe-base binary alloys, like those with nickel or manganese, strongly suggests that the atomic mechanisms by which the transformation takes place in the two classes of alloys are very similar, and the Ti-Mo transformation would be of the martensitic type. Obviously, the results of the present investigation do not demonstrate that all the characteristic features of a martensite reaction exist in the Ti-Mo system. However, since the reaction takes place, at least partially, at rates of cooling of the order of 10,000°C per sec, it is difficult to refute the conclusion that the reaction is diffusionless. In addition, it was shown that the temperature at

Fig. 9—Typical martensite-like structure in a Ti-Mo alloy (5 pct Mo) quenched from 980°C.

which the reaction takes place is independent of the rate of cooling. Therefore, two important characteristics of the martensite reaction have been found in Ti-Mo alloys.

It may be of interest also to point out that in some cases micrographs showing the typical structure of martensite needles have been obtained. Fig. 9 shows a Ti-Mo alloy containing 9.5 pct Mo prepared with titanium powder obtained from the Bureau of Mines and quenched from the  $\beta$  field.<sup>†</sup> The rather large  $\alpha'$  needles in a  $\beta$  matrix are very similar to martensite in austenite. The occurrence of well-defined isolated needles, as shown in Fig. 9, was rather rare in the specimens studied in the present investigation, probably because too large a portion of the  $\beta$  phase was transformed. There is probably a critical and narrow range of molybdenum concentration for which only a small fraction of the  $\beta$  phase would be transformed by quenching to room temperature, and in this range more typical martensitic needles could likely be obtained.

The thermal analysis method used in this investigation is not suitable for a complete study of the finer details involved in a martensite reaction. It is probable that there is a temperature interval between the beginning and the end of the reaction. By thermal analysis, it is possible to detect only the temperature at which the bulk of the heat is released. This temperature probably corresponds to that which is sometimes referred to as the burst temperature for the martensite reaction.

Finally, the atomic mechanism of the transformation in titanium alloys of the Ti-Mo type remains unknown. The only clue to a possible mechanism is the work of Burgers on the crystallographic relationships in the transformation of pure zirconium.<sup>18</sup>

### Conclusions

1—The temperature at which titanium transforms from the  $\beta$  form (body-centered cubic) to the room temperature  $\alpha$  form (hexagonal close-packed) decreases progressively from 882°C to about 850°C with increasing rate of cooling from 4° to 10,000°C per sec. A similar effect has been found for zirconium, for which the drop in temperature is from 865° to 850°C. The transformation temperature of thallium (also from body-centered cubic to hexagonal close-packed) is not affected by rates of cooling up to 8000°C per sec. The body-centered cubic to hexagonal close-packed transformation in these three metals is therefore a diffusionless transformation and is probably the result of a combination of shear and homogeneous change in volume.

2—The solid state phase boundaries in the Ti-Mo system have been established above 650°C. Alloys quenched from the  $\beta$  field transformed into an  $\alpha$  supersaturated solid solution (called  $\alpha'$ ) for molybdenum concentration up to about 12 pct. The transformation is only partial from about 4 to 12 pct Mo. Above 12 pct Mo, the  $\beta$  structure is retained.

3—From 0 to 8 pct Mo, the temperature at which  $\beta$  transforms entirely or partially to  $\alpha'$  was measured by thermal analysis. This temperature is not affected by the rate of cooling. For molybdenum concentration between 8 and 12 pct, no heat effect was detected during cooling although it was found by both X-ray diffraction and microscopy that  $\alpha'$  was present

after quenching. The heat released in the case of partial transformation was probably too small to be detected by thermal analysis.

4—The analogy between the Ti-Mo alloys and some binary Fe-base alloys (such as iron with nickel or manganese) suggests that the transformation in the Ti-Mo system is of the martensite type. The same type of transformation has been found in the Ti-Cr system and probably exists in other binary alloys for which there is an extensive solid solubility in  $\beta$  titanium.

### Acknowledgment

This work was sponsored by the Office of Naval Research, U. S. Navy, under contract number N6ONR-24430. The author wishes to express his appreciation to I. R. Kramer, Head, Materials Branch, Office of Naval Research, who pointed out the importance of the kinetics of the phase transformation in titanium alloys. Thanks are also due to D. S. Clark for his valuable cooperation and to J. O. McCaldin, J. M. Denney, and W. V. Wright, Jr., who carried out most of the experiments.

<sup>†</sup> Such specimens prepared by powder metallurgical methods were not as pure as those used for the phase diagram study and the presence of impurities might have had an effect on the microstructure.

# Crystal Structure of $\text{Ti}_5\text{Si}_3$ , $\text{Ti}_5\text{Ge}_3$ , and $\text{Ti}_5\text{Sn}_3$

by Paul Pietrokovsky and Pol Duwez

The crystal structure of the compound  $\text{Ti}_5\text{Ge}_3$  has been determined from X-ray powder diffraction data. Related silicon and tin compounds have been found to be isomorphous. Unit cell dimensions, axial ratios, and parameters for equivalent atomic positions are given.

THERE is, at present, only meager information pertaining to the solid state reactions of titanium with the elements in group 4B of the periodic table (silicon, germanium, tin, and lead). The only two compounds whose crystal structure has been established are  $\text{TiSi}_2$  and  $\text{TiGe}_2$  (references 1 and 2 respectively). These two compounds are isomorphous and have an orthorhombic symmetry  $D_{2h}^{28} - Fddd$ . The titanium-rich regions of the constitution diagrams of titanium-silicon, titanium-tin, and titanium-lead have been investigated by Craighead et al.<sup>3</sup> While valuable information concerning the alpha solid solubility of these three elements in titanium was obtained, no light was shed on the existence or nature of the titanium-rich compound in these systems. The present study is concerned with the crystal structure of the intermediate phases  $\text{Ti}_5\text{Si}_3$ ,  $\text{Ti}_5\text{Ge}_3$ , and  $\text{Ti}_5\text{Sn}_3$ , which were found to be isostructural.

The alloys were prepared by mixing the pure metal powders in the desired proportions, pressing the mixture into pellets, and melting them in an electric arc furnace in the presence of a helium atmosphere.<sup>4</sup> After melting, the specimens, weighing approximately 5 g, were sealed in evacuated quartz vials, homogenized at 1038°C for three days, and quenched from that temperature. Powder diffraction patterns were made with a 143.2 mm diam Debye-Scherrer X-ray camera in which the Ievins and Straumanis film arrangement was utilized. Filtered copper radiation was used throughout the entire investigation.

A study of the powder patterns of a series of alloys of various compositions indicated the presence of a compound around a composition corresponding approximately to a ratio of 3 titanium to 2 silicon, germanium, or tin. From a visual examination of the diffraction patterns, it was evident that the silicon and germanium alloys were iso-

morphous. For small angle reflections, the powder pattern of the tin compound was analogous to that of the silicon and germanium compounds, but after the first ten reflections, the similarity was no longer clear. The powder pattern of the germanium compound was selected for indexing, since it exhibited a weak small angle reflection and clearly resolved doublets in the back-reflection range. Good agreement between observed and calculated values of  $(1/d)^2$  was found by indexing the pattern on the basis of hexagonal symmetry. For the hexagonal system:

Table 1. Debye-Scherrer Powder Diffraction Data for  $\text{Ti}_5\text{Ge}_3$ .  
Filtered Copper Radiation.

Discussion on this paper, TP 3121E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 10, 1951. Detroit Meeting, October 1951.

$$(1/d)^2 = A(h^2 + hk + k^2) + B(1)^2 \quad [1]$$

$$A = \frac{4}{3a^2}, \quad B = \frac{1}{c^2}$$

The results of these computations are shown in Table I.

A similar method of indexing was applied to the titanium-silicon and titanium-tin compounds, and in all cases, good agreement was obtained between calculated and observed interplanar spacings. The values of the constants  $A$  and  $B$  in the quadratic eq 1 and the lattice parameters of the three compounds are given in Table II. The parameters were ob-

Table II. Unit Cell Parameters for  $Ti_5Si_3$ ,  $Ti_5Ge_3$ , and  $Ti_5Sn_3$ . Parameters are expressed in Å.

| Compound   | A      | B      | $a_0$             | $c_0$             | $c_0/a_0$ |
|------------|--------|--------|-------------------|-------------------|-----------|
| $Ti_5Si_3$ | 0.0239 | 0.0375 | $7.465 \pm 0.002$ | $5.162 \pm 0.002$ | 0.692     |
| $Ti_5Ge_3$ | 0.0235 | 0.0367 | $7.537 \pm 0.002$ | $5.223 \pm 0.002$ | 0.693     |
| $Ti_5Sn_3$ | 0.0258 | 0.0336 | $8.049 \pm 0.002$ | $5.454 \pm 0.002$ | 0.678     |

tained by applying the least squares method to the large angle reflections.

An attempt to elucidate the structure of the titanium-germanium compound was made on the basis of the powder pattern. The only systematic extinctions in the Debye-Scherrer patterns are those of the  $(h0l)$  reflections for  $l \pm 2n$ . This indicates the presence of a mirror glide plane with a displacement  $c/2$  parallel to the  $c$  axis. Since no other systematic extinctions were observed, five space groups are possible, namely  $D_{3d}^4$ ,  $C_{3v}^{18}$ ,  $D_{6h}^8$ ,  $C_{6v}^{18}$ , and  $D_{3h}^6$ . Since a further reduction in the number of likely space groups is not possible from the powder data, it was decided to initiate a survey of the literature prior to finding the Laue symmetry. This survey failed to uncover any similitude with a compound of the  $A_3B_2$  type, but an analogy was found with  $Mn_5Si_3$ . The structure of  $Mn_5Si_3$ , determined by Åmark, Borén, and Westgren,<sup>5</sup> is hexagonal and belongs to the space group  $D_{3h}^6 - C 6/mcm$  (type  $D8_3$ ). The unit cell contains 16 atoms in the following positions.\*

4 Mn I in  $(d)$ :  $1/3 \ 2/3 \ 0$ ;  $2/3 \ 1/3 \ 0$ ;  $1/3 \ 2/3 \ 1/2$ ;  $2/3 \ 1/3 \ 1/2$ .

6 Mn II in  $(g)$ :  $x0\frac{1}{4}$ ;  $0x\frac{1}{4}$ ;  $\bar{x}\bar{x}\frac{1}{4}$ ;  $\bar{x}0\frac{3}{4}$ ;  $0x\frac{3}{4}$ ;  $xx\frac{3}{4}$ .

$x = 0.23$ .

6 Si in  $(g)$ :  $x = 0.60$ .

A perspective drawing of the structure is shown in Fig. 1.

Assuming this structure to be the correct one for the titanium-germanium compound, intensity computations were made using the well-known formula:

$$I = \text{constant} [F(hkl)]^2 p \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta}$$

In view of the large number of reflections present (57 for  $Ti_5Ge_3$ ), no correction for absorption was included in the calculated intensities. Only the first reflection (100) suffers greatly from this oversight. With the exception of the (100) reflection, the agreement between calculated and observed intensities (Table II) is quite satisfactory. Similar com-

\* An error in the tabulation of nearest neighbors to the silicon atom in the position  $[\bar{x}\bar{x}\frac{1}{4}]$ ,  $x = 0.60$ , should be corrected in ref. 6. The atom designated  $f'$  and the two atoms marked  $f''$  are Mn II atoms and not Si atoms; the number of nearest neighbors to the silicon atoms having the structural symmetry  $C 2v - mm$  are 4 Mn I atoms, 3 Mn II atoms, and 6 Si atoms.

Fig. 1—Perspective drawing of two cells of  $Ti_5(Si, Ge, Sn)_3$  (lower left) and of one cell expanded in the  $c$  axis direction (upper right).

putations were made for  $Ti_5Si_3$  and  $Ti_5Sn_3$ , and in all cases, the observed intensities were in good agreement with the calculated values.

From the point of view of a systemization of the structure of intermetallic compounds between the transition elements of the first series and the elements of the 4B group of the periodic table, it is interesting to note that the only other intermetallic compound reported so far as being isomorphous with  $Mn_5Si_3$  is the  $\eta$  phase ( $Fe_5Si_3$ ) in the iron-silicon system.<sup>7,8</sup> It is probable that other compounds of the  $Mn_5Si_3$  type exist between the transition elements and silicon, germanium, and tin.

# Role of Gases in the Production of High Density Powder Compacts

by Donald Warren and J. F. Libsch

THIS investigation originated as a result of a previous experimental study<sup>1</sup> of the magnetic properties of Fe-Co alloys fabricated by the powder metallurgy technique. Densities of powder compacts prepared for the magnetics investigation varied from 7.45 to 7.70 g per cu cm or from 93 to 95 pct of the experimental value of 8.08 g per cu cm for a fused alloy of the same composition.<sup>2</sup> While this range of density is considered sufficiently high for most applications, the highest possible density is to be desired for maximum magnetic properties.

By applying a technique similar to the one described above to a pure electrolytic iron powder, Rostoker<sup>3</sup> was able to achieve a density of 7.895 g per cu cm, which is the highest density ever reported for sintered iron. While Rostoker's work involved the sintering of an elemental powder rather than a mixture, it was believed that higher densities should also have been obtained for alloys using the above technique because of the recoining operation and the high sintering temperature. Consequently, it was decided to investigate the various factors affecting the density of this alloy with the idea that such a study might lead to higher densities and, as a result, powder alloys having magnetic properties identical with those of the fused alloys.

It was believed that the principal reason that near-theoretical densities for the powdered alloy were not obtained was the interference of gases with the normal sintering mechanism. When present during the sintering operation, gases can exert several harmful effects: they can remain on the particle surface and interfere with surface diffusion and plastic flow; they can be released and, under certain conditions, expand the void spaces through gas pressure; or they can remain trapped in the pores and exert a hydrostatic pressure that retards elimination of the pores.

Jones,<sup>4</sup> Rhines,<sup>5</sup> Goetzel,<sup>6</sup> and others have given the effect of gases in the sintering of powder compacts an extensive treatment. Among the more important sources of gases in the sintering process are dissolved gases, adsorbed gases, air entrapped during pressing, and gaseous products of chemical reactions. During sintering adsorbed gases are partly released at a relatively low temperature, while those gases entrapped during pressing cannot escape until their pressure is increased sufficiently through increasing temperature to expand the interparticle openings. The remaining adsorbed gases, gaseous reduction products, and dissolved gases produce a similar effect at the higher temperatures. If, in the

sintering process, gas evolution occurs after the inter pore channels have been sealed, an exaggerated expansion of the void spaces results. This is particularly true if the temperature is high enough for extensive plastic flow.

In his fabrication of powder bars from tantalum, Balke<sup>7</sup> had to consider the effect of adsorbed hydrogen and provide for its escape during sintering by limiting the compacting pressure to a maximum of 50 tons per sq in. The effect of gases entrapped during pressing was first noted by Trzebiatowski<sup>8</sup> when he found that gold and silver powders decrease in density with increasing sintering temperature if pressed at 200 tsi, while they exhibit the usual increase when pressed at 40 tsi. Recent investigators<sup>9-11</sup> have also noted that entrapped gases have an effect on the expansion of copper compacts during sintering. Proper provision for the escape of gaseous products of reduction must be made in order to avoid deleterious effects. Myers<sup>12</sup> states that in the sintering of electrolytic tantalum powder, the temperature was gradually raised to 2600°F with a pause at 2000°F to permit reduction of the oxides.

## Experimental Details

For the present study, 50 pct Co-50 pct Fe compacts in the form of circular disks 1½ in. in diam and 0.15 in. thick were fabricated by the pressing and sintering of a mixture of the elemental powders. It was decided to follow the sintering process by means of liquid permeability measurements, because it was thought that such measurements might serve as a measure of relative pore sizes, as well as a possible indication of the point at which most of the inter pore channels become sealed. However, since the permeability as measured by the flow of a liquid, such as ethylene glycol, does not give an absolute indication of the point where the pores have become isolated, a method for determining the percentage of pores connected to the surface was set up. As an additional cross check on the permeability measurements, metallographic methods were used to study the relative pore size. Finally, the property of ultimate interest, the density, was measured.

**Raw Materials:** The powders used consisted of an annealed, 99.9 pct pure, -150 mesh grade of electrolytic iron powder, and a 98 pct pure, -200 mesh grade of reduced and comminuted cobalt powder. The cobalt powder was not further processed either by hydrogen reduction or annealing.

The screen analyses for the iron and cobalt powders are given in Table I, while the chemical analyses for each type of powder are listed in Table II. Table III gives the hydrogen loss measurements for the powders according to the M.P.A. Standard Method and for a higher temperature as well.

**Preparation of Compacts:** Equal amounts of the elemental powders were mixed by rotation for 1 hr and then pressed into compacts approximately 0.15

Discussion on this paper, TP 3135E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 16, 1951; revision, July 12, 1951. Detroit Meeting, October 1951.

Table I. Screen Analyses of Powders

| Size Range | Fe Powder, Pct | Co Powder, Pct |
|------------|----------------|----------------|
| +80 mesh   | Trace          | Trace          |
| -80 +100   | Trace          | Trace          |
| -100 +150  | Trace          | Trace          |
| -150 +200  | 8.75           | Trace          |
| -200 +325  | 22.80          | 0.96           |
| -325       | 68.40          | 99.00          |

in. thick in a single acting die lubricated with a 3 pct stearic acid solution. The equipment used for pressing and sintering the compacts has been described previously.<sup>8</sup> It should be mentioned that the compacts, except where otherwise stated, were placed in the furnace directly at the sintering temperature and required about 5 to 10 min to reach temperature.

**Permeability Measurements:** The permeability of the compacts was measured by a method similar to the one devised by Chadwick and Broadfield.<sup>18</sup> The apparatus consisted of a Witt filter flask in which was mounted a filter funnel feeding into a graduated cylinder inside the flask. When the flask was evacuated with a Cenco Hy-Vac pump, the atmospheric pressure caused the compact to seat itself against a thin rubber sleeve placed in the filter funnel and thus provide an air-tight connection. Ethylene glycol was used as the permeating medium because of its low viscosity and vapor pressure and lack of corrosive action. The time required for 5 ml of glycol at a temperature of 30°C to pass through a compact of approximately 0.15 in. thickness under a pressure difference of more than 75 cm of mercury was measured. In some instances where the permeability was very low and the times required were very long, the measurement was limited to only 2 or 3 ml of flow. In all cases, the permeability was reported as ml per in.<sup>2</sup> min where in.<sup>2</sup> refers to the surface area of the compact.

**Pore Volume and Density Measurements:** After a compact had been given its final fabricating treatment, it was cleaned in acetone, oven-dried, and weighed on an analytical balance. The compact was then immersed in xylene and a vacuum pulled on it to remove the air from the pores and allow the xylene to enter. The weight of the compact in xylene, maintained at a temperature of 30°C ±1°C, was then measured. After being oven-heated to drive off the xylene, the compact was given several applications of Dekadhesse to provide a thin coating that was impervious to water. Next, the coating was oven-baked, and finally, the weight of the compact in air and in water was determined. Those compacts which had densities equal to 95 pct or more of the theoretical density were not coated with Dekadhesse but were weighed directly in water.

The following is an outline of the method used for calculating pore volume and density from the measurements described above:

$$\text{Bulk volume of the compact} = \frac{W_{CA} - W_{CW}}{D_W} \quad [1]$$

Table II. Chemical Analyses of Powders

|           | C, Pct | Mn, Pct | Si, Pct | Cu, Pct | Ni, Pct |
|-----------|--------|---------|---------|---------|---------|
| Fe powder | 0.048  | 0.04    |         |         |         |
| Co powder | 0.069  | 0.11    | 0.13    | 0.075   | 0.5     |

where  $W_{CA}$  is the weight of compact in air after coating with Dekadhesse;  $W_{CW}$ , the weight of compact in water after coating with Dekadhesse; and  $D_W$ , the density of water at temperature of measurement.

$$\text{Subsurface volume of the compact (volume of the metal itself plus isolated pores)} = \frac{W_A - W_x}{D_x} \quad [2]$$

where  $W_A$  is the weight of compact in air;  $W_x$ , the weight of compact in xylene; and  $D_x$ , the density of

Table III. Hydrogen Loss Measurements

|                          | Fe Powder, Pct | Co Powder, Pct |
|--------------------------|----------------|----------------|
| 1 hr at 1050°C           |                |                |
| (Standard M.P.A. Method) | 0.4            | 1.3            |
| 30 min at 1400°C         | 0.4            | 1.4            |
| 1 hr at 1400°C           | 0.4            | 1.4            |

xylene at temperature of measurement (for these experiments  $D_x = 0.855$  g per cu cm at 30°C).

$$\text{Volume of surface connected pores} = \frac{W_{CA} - W_{CW}}{D_W} - \frac{W_A - W_x}{D_x} \quad [3]$$

$$\text{Volume of metal alone} = \frac{W_A}{8.08} \quad [4]$$

where 8.08 g per cu cm is the density of the fused 50 pct Fe-50 pct Co alloy.<sup>2</sup>

$$\text{Total volume of the pores} = \frac{W_{CA} - W_{CW}}{D_W} - \frac{W_A}{8.08} \quad [5]$$

$$\text{Density of the compact} = W_A \div \frac{W_{CA} - W_{CW}}{D_W} \quad [6]$$

The densities of those compacts which had to be coated with Dekadhesse before weighing in water are accurate only to about 0.01 g per cu cm because of the error introduced by the coating. However, for those compacts having a density equal to or greater than 95 pct of the theoretical density, the density is correct to 0.001 g per cu cm.

In the experimental results the volume of the surface connected pores is expressed as a percentage of the total pore volume. The accuracy of this value depends upon the error introduced by the Dekadhesse coating in the bulk volume measurement and as such it varies with the total amount of porosity. Where the total porosity is high, the percentage of surface connected pores is correct to ±1 pct and where the total porosity is low, this value is correct only to ±5 pct.

**Metallographic Examination:** The samples for metallographic examination were first impregnated with a very thin varnish and oven-baked. After being ground and polished, the compacts were electrolytically etched in a 10 pct nitric acid solution in order to remove the flowed metal covering the pores and then etched for 2 to 3 min by immersion in a 4 pct picral solution to reveal the grain boundaries.

### Experimental Observations on Compacting and Sintering Procedures

**Effect of Compacting Pressure:** The effect of compacting pressure upon the permeability, density, and percentage of pores connected to the surface of green compacts is shown in Fig. 1.

The fact that practically 100 pct of the pores are connected to the surface in specimens compacted at

Fig. 1—Effect of compacting pressure.

pressures up to 75 tsi indicates that there is little likelihood of entrapped gases in these compacts. This is in accordance with the views of Kamm, Steinberg, and Wulff,<sup>9</sup> who feel that there is very little possibility of entrapping gases during the pressing of relatively hard powders, such as iron and nickel.

Figs. 2 and 3 are micrographs of compacts pressed at 25 and 75 tsi, respectively. (It was necessary to sinter these compacts at 800°C for metallographic preparation.) The larger particles of iron are most prominent, while the lighter areas consist of the finer particles of iron and cobalt which have already begun to sinter.

*Effect of Sintering Time and Temperature upon Compacts Pressed at 25 tsi:* The results of these experiments are summarized in Figs. 4 and 5. It is important to stress the fact that none of the increases in permeability would be predicted if the sintering process were being followed by means of density measurements alone, as can be seen from the lower set of curves in Fig. 5. The only irregularity observed in the density vs. sintering time curves is that the entire curve for 1000°C lies below that for 800°C. This apparent anomaly has been noted by other investigators<sup>11, 14</sup> and has been attributed to various factors connected with the  $\alpha$  to  $\gamma$  phase transformation.

While a study of the density values gives no

Fig. 2—Pressed at 25 tsi, sintered 15 min at 800°C. X100.

Fig. 3—Pressed at 75 tsi, sintered 15 min at 800°C. X100.

Fig. 4—Effect of sintering time and temperature upon the permeability of compacts pressed at 25 tsi.

Fig. 5—Effect of sintering time and temperature upon the density and pore volume of compacts pressed at 25 tsi.

reason for the increases observed in the permeability values, metallographic examination does. Figs. 6, 7, 8, and 9 are micrographs of compacts sintered 1 hr at 800°, 1000°, 1200°, and 1400°C, respectively. It can be seen that the individual pores become increasingly well-defined with increasing sintering temperature, and that those pores in the compact sintered at 1400°C have been blown up tremendously. Metallographic examination showed that the microstructure of the compact sintered 3 hr at 1200°C was essentially the same as that of Fig. 8.

Since the individual pores have been expanded to a greater extent after an hour sinter at 1400°C than after a similar sinter at 1200°C, it might be expected that the permeability values for the former will be greater than those for the latter. But such is not the case. In order to resolve the apparent disagreement, it should be remembered that the resistance of a powder compact to liquid flow in a permeability measurement depends not only upon the pore size but also upon the degree to which the pores are interconnected. It is here that a metallographic study fails to tell the complete story. It would be expected that at 1400°C, the interpore channels would be sealed more rapidly than at 1200°C. This is borne out by the following observations: 1—the greater expansion of individual pores at 1400°C, which requires the prior sealing of interpore channels; 2—the absence in Fig. 9 of the network of fine pores present in Fig. 8; and 3—the large decrease in percentage of pores connected to the surface for compacts sintered more than 4 hr at 1400°C, Fig. 5. From the above discussion, it can be seen that the permeability value for a powder compact depends upon the balance between the shrinkage produced by normal sintering and the expansion due to the presence of evolved gases.

Fig. 6—Pressed at 25 tsi, sintered 1 hr at 800°C. X100.

Fig. 7—Pressed at 25 tsi, sintered 1 hr at 1000°C. X100.

Fig. 8—Pressed at 25 tsi, sintered 1 hr at 1200°C. X100.

Fig. 9—Pressed at 25 tsi, sintered 1 hr at 1400°C. X100.

Of the sources of gases in the sintering process, it is believed that chemisorbed gases and gaseous reduction products are primarily responsible for the pore expansion observed in compacts sintered at 1200° and 1400°C. Some idea of the oxide content of the cobalt and iron powders can be obtained from the hydrogen loss values given in Table III. The existence of such oxides, either as surface films or inclusions in the powder, is detrimental because the reduction of oxides by hydrogen used as a sintering atmosphere or by carbon in the powders themselves (see Table II) will lead to the evolution of gases. The detrimental effect of oxides has been shown by Cordiano,<sup>15</sup> who obtained a decrease in density with increase in hydrogen loss for iron compacts sintered for short times. The reduction of cobalt and iron oxide by hydrogen begins below 500°C and is rapid at 700° to 1100°C. The fact that reduction occurs at these higher temperatures means that oxides probably contribute more to pore expansion than any other source of gases, because their gaseous reduction products must make their escape after considerable sintering (sealing of the inter pore channels) has occurred.

There is no data to show the amount of chemisorbed gases present in the powders used for this study. However, Taylor and Burns<sup>16</sup> have studied the adsorption of gases by iron and cobalt powders. Their data indicate that appreciable quantities of CO and CO<sub>2</sub> were adsorbed by cobalt powder, while only small quantities were adsorbed by iron powder. It was also indicated that there was considerably more adsorption by a partially oxidized lot of cobalt powder than by a completely reduced lot of the same powder. Since their adsorption values decrease with increasing temperature, it is reasonable to expect that in the heating of a green compact, the bulk of adsorbed gases would be driven off before appreciable sintering could occur. Whether or not the escape of such gases expands the pores depends upon the degree of powder compaction and the heating rate during sintering. In the case of the present experiments, the compacts were placed in the furnace at the sintering temperature and required only 5 to 10 min to reach that temperature. With such a high heating rate, the presence of adsorbed gases becomes significant.

*Effect of Sintering at 1400°C upon Compacts Pressed at 25, 50, and 75 tsi:* The results of these experiments are presented in Fig. 10. A study of this figure shows that for the first time, the pore expansion (as indicated by an increase in permeability)

could be detected by a decrease in density. However, this was true only of the density curve for a pressure of 75 tsi. It is important to note that the density values after a 24 hr sinter at 1400°C decrease in order of increasing compacting pressure, which is just the opposite of what might be expected.

That the early increases in the permeabilities are caused by expansion of the pores is borne out by Figs. 11 and 12, which present a clear picture of the relative pore sizes in compacts pressed at 25 and 50 tsi, respectively, and then sintered for 30 min at 1400°C. The microstructure of the compact pressed at 75 tsi and sintered 30 min at 1400°C was similar to that of Fig. 12. Because the compacts pressed at 25 tsi were more porous in the green condition than the compacts pressed at 50 and 75 tsi, the individual pores have not been blown up to as great an extent in these as in the denser compacts.

The lesser degree of pore expansion in compacts pressed at 25 tsi is reflected in Fig. 10 by the more rapid decrease in permeability and in the percentage of pores connected to the surface between 1 and 2½ hr at 1400°C for compacts pressed at 25 tsi.

Fig. 10—Effect of sintering at 1400°C on compacts pressed at 25, 50 and 75 tsi.

Fig. 11—Pressed at 25 tsi, sintered 30 min at 1400°C. X100.

Fig. 12—Pressed at 50 tsi, sintered 30 min at 1400°C. X100.

The lesser expansion of individual pores that occurs with the lower compacting pressures can be attributed to two factors: 1—the hydrogen has greater access to the surfaces of loosely compacted powder particles, and 2—the slower initial rate of sintering provides a greater opportunity for the oxides to be reduced and for the gaseous reduction products to escape. In the highly compressed compacts, sealing of the interpore channels begins earlier and takes place more rapidly. In such a case, the relatively small hydrogen atoms can easily diffuse into the interior of the compact, but the larger molecules of water formed by the reduction cannot diffuse outward through the lattice interstices. Thus, they must remain in the sealed off pores to either produce an actual expansion or to retard sintering.

The decrease in final density that occurs with an increase in compacting pressure for compacts sintered 24 hr at 1400°C is a reflection of the larger degree of pore expansion with the higher compacting pressures, because these larger pores are closed up at a very slow rate. Also, there is a greater possibility with the higher compacting pressures of gases being sealed off in the pores and thus retarding the later phases of sintering. Both Shaler<sup>17</sup> and Mackenzie and Shuttleworth<sup>18</sup> have given the effect of gases trapped within the pores of powder compacts an extensive mathematical treatment.

### Study of the Gases Evolved During Sintering

In the second phase of this investigation, an effort was made to relate the effects observed in the orig-

Fig. 13—Effect of sintering at 1400°C in hydrogen and helium on compacts pressed at 50 tsi.

inal experimental results with the evolution of gases and to determine, if possible, the nature of these gases.

**Effect of Sintering at 1400°C in Hydrogen and Helium on Compacts Pressed at 50 tsi:** Since it was believed that gases resulting from the reduction of oxides in or on the powder particles by the hydrogen of the sintering atmosphere was primarily responsible for the expansion of the pores, a series of compacts was pressed at 50 tsi and sintered at 1400°C in a helium atmosphere for comparison with the previous series of compacts pressed at 50 tsi and sintered at 1400°C in hydrogen. The results of this experiment are shown in Fig. 13.

The large increase in the permeability, as well as the significant decrease in the density, of a compact sintered at 1400°C in helium suggests the occurrence of a severe expansion of the individual pores leading to an overall growth in the size of the compact. That such is actually the case is shown by the microstructure of a compact pressed at 50 tsi and sintered for 30 min at 1400°C in helium, see Fig. 14.

Fig. 14—Pressed at 50 tsi, sintered 30 min at 1400°C in helium. X100.

This experiment tends to relegate the effect of chemisorbed gases to a relatively minor role as far as pore expansion is concerned, because if chemisorbed gases, alone, were responsible for the effects observed, then there seems to be no obvious reason why the properties of compacts sintered in hydrogen and helium would not be fairly similar. The most logical explanation for the results observed for compacts sintered in helium seems to be that the gases were produced either by the reduction of oxide films by carbon in the powders or by thermal decomposition of the oxides.

Reduction of the oxides by carbon would probably be slower than reduction by hydrogen, because the diffusion of carbon is necessary for appreciable reduction to occur, whereas hydrogen can readily permeate the pores of the compact. According to the available data,<sup>19</sup> the only oxide of either cobalt or iron that decomposes at 1400°C or below is cobaltic oxide ( $\text{Co}_2\text{O}_3$ ) which decomposes at 895°C. Such a thermal decomposition would therefore occur at a temperature higher than that required for reduction by hydrogen. Thus, either of the two proposed mechanisms would lead to the evolution of gases at a later stage in the sintering process than if the same gases had been liberated by reduction of the oxides by hydrogen. This evolution of gases after appreciable sintering (sealing of interpore channels) had already occurred seems to account for the greater expansion of pores observed for the compacts sintered in helium.

**Effect of Sintering at Various Temperatures in**

**Helium on Compacts Pressed at 50 tsi:** In order to determine if gases were actually being evolved by the thermal decomposition of oxides contained in the powders, the oxygen content of compacts pressed at 50 tsi and sintered for 4 hr in helium at 1100°, 1200°, 1300°, and 1400°C was determined by means of vacuum-fusion analyses. A 4 hr time limit was chosen, because it was believed that the largest part of any thermal decomposition would have occurred in that length of time. As a basis for determining the original oxygen content of the compacts, vacuum-fusion analyses for oxygen were made on a compact pressed at 50 tsi and sintered in helium for 15 min at 800°C and also on a green compact of the same powder mixture. In conjunction with the vacuum-fusion analyses, the usual measurements were also made. These data are presented in Fig. 15.

The results of the vacuum-fusion analyses are expressed in terms of the original oxygen content of the green compacts (0.84 pct O) as determined by vacuum fusion. The fact that sintering 4 hr at 1100° and 1400°C in helium has eliminated 53 and 86 pct, respectively, of the original oxygen content of the compacts clearly indicates that gases are evolved during the sintering process.

Fig. 15—Effect of sintering at various temperatures in helium on compacts pressed at 50 tsi.

In Fig. 15, the evolution of gases is also reflected by the rapid increase in permeability between 1200° and 1400°C accompanied by a small decrease in density and a small increase in the percentage of pores connected to the surface. The main reason for the difference between the properties of compacts sintered for 4 hr at 1200°C and for 4 hr at 1300° or 1400°C would seem to be due to the greater plasticity of the metal at the higher temperatures, because the difference in the amount of gas liberated at each of these three temperatures is obviously not enough to account for it. The fact that the expansion of individual pores has occurred during the sinter at 1200°C, but to a lesser extent than that at 1400°C, is shown by a comparison of Figs. 16 and 17.

**Effect of Heating Cobalt Powder to 1000°C in a Vacuum:** Because the cobalt powder had a hydrogen loss three times that for the iron powder (see Table III) and because its oxygen content by vacuum-fusion analysis was 1.04 pct compared to 0.41 pct

Fig. 16—Pressed at 50 tsi, sintered 4 hr at 1200°C in helium. X100.

Fig. 17—Pressed at 50 tsi, sintered 4 hr at 1400°C in helium. X100.

for the iron powder, a study was made of the evolution of gases upon heating from the cobalt powder alone. This was done by degassing in a vacuum a 4 g sample of cobalt powder for 2 hr at 225°C, sealing off the system at a vacuum of  $10^{-6}$  cm after degassing, and then measuring the pressure of the closed system as the cobalt powder was gradually heated (5°C per min) from 250° to 1000°C (the upper temperature limit of the apparatus). The results of this experiment, which are given in Fig. 18, show that rapid gas evolution occurs between 350° and 450°C and between 800° and 1000°C.

The volume of gas liberated upon heating to 1000°C was calculated to be 1.6 ml per g of cobalt powder. While this is an appreciable quantity of gas, it represents less than one fourth of the total gas available (7.3 ml per g) as calculated on the basis of the vacuum-fusion analysis (1.04 pct O). Vapor pressure and chemical solubility measurements showed that the gas evolved from the cobalt powder was largely carbon dioxide.

This carbon dioxide could be formed by the reaction between the carbon and oxides of the powders or by the release of chemisorbed gases. In their study of gas evolution on rise of temperature for carbonyl iron powder, Duftschmid, Schlecht, and Schubardt<sup>20</sup> found that the reaction between the carbon and iron oxide of the powders produced a major gas evolution at 450°C with the bulk of the gas being carbon dioxide with some carbon monoxide also present.

If all the carbon (0.069 pct) present in the cobalt powder were oxidized to carbon dioxide during the heating to 1000°C, then 1.3 ml of carbon dioxide per gram of powder would be produced. This leaves 0.3

Fig. 18—Pressure of liberated gas vs. temperature for cobalt powder heated in a vacuum.

ml to be supplied by some other source, such as chemisorbed carbon dioxide.

The above discussion leads to the belief that the evolution of gas from the cobalt powder occurring at 400°C is largely due to the reduction of oxides by carbon in the powder and that the second evolution occurring at 800° to 1000°C is probably the result of the thermal decomposition of cobaltic oxide (decomposes at 895°C).

### Minimizing the Influence of Gases on Sintering Process

The final part of this investigation consisted of experiments that were designed to minimize or even eliminate, if possible, the influence of gases upon the sintering process.

*Effect of Reduction of Powder upon Influence of Gases during Sintering:* The most obvious method of minimizing the influence of gases upon the sintering process is to eliminate the source of these gases. An attempt was made to accomplish this purpose, first by reduction of the cobalt powder alone (because of its higher oxygen content) and then by reduction of both the iron and the cobalt powder just prior to compacting and sintering.

A series of compacts were prepared from cobalt powder, annealed in pure dry hydrogen for 1 hr at 600°C, and unannealed iron powder by pressing at 50 tsi and sintering for 30 min and for 24 hr at 1400°C. The properties of these compacts along with the properties of compacts fabricated in a similar manner from both unannealed cobalt and iron powder are listed in Table IV for comparison. The fact that the prior reduction of cobalt powder resulted in a lower permeability and a higher density for the compacts sintered 30 min at 1400°C would certainly seem to indicate that less pore expansion had occurred, and that, as a result, a higher density might be obtained for similar compacts sintered 24 hr at 1400°C. But as can be seen, this is not the case.

A glance at the microstructure of a compact prepared using the annealed cobalt powder and sintered for 30 min at 1400°C helps to resolve this difficulty, see Fig. 19. It should be noted that even though the hydrogen loss for the powders used in making the compact was reduced to one third of its original value by the prior reduction, the pores have still been enlarged sufficiently to interfere with the achievement of a high final density (24 hr at 1400°C).

In order that the maximum amount of gases might

be eliminated prior to sintering, both the iron and the cobalt powder were annealed for 1 hr at 600°C in pure dry hydrogen, and a series of compacts were pressed at 25 tsi and sintered 24 hr at 1400°C. As shown in Table IV, even this reduction treatment did not result in a higher final density.

*Effect of Variations in Sintering Cycle to Allow for Removal of Gases from Compacts:* Because the minimization of the deleterious effects of gases by variation in the sintering cycle had been successfully carried out by other investigators,<sup>12</sup> it was decided to use two such methods in order to eliminate the gases from the compacts before the inter pore channels could become sealed. The first method was to place the compacts in the furnace at 800°C and heat slowly (2.5° to 3° per min) from 800° to 1400°C in order to allow the oxides to be gradually reduced with the gaseous reduction products making their escape while the inter pore channels are still open. The second method was to place the compacts in the furnace at 800°C and hold at that temperature for 4 hr in order to provide for the maximum reduction of oxides before the sintering temperature was increased to 1400°C. At 800°C the gaseous reduction products can make their escape without disrupting the compact because the sintering action is relatively slow.

The results of these two experiments which are given in Table V show that both of the treatments described above have had a very beneficial effect in increasing the density. While the second method of varying the sintering cycle decreased the sintering time at 1400°C to 19 hr, it still resulted in higher final densities, even in the case of those compacts pressed at 25 tsi and having a low green density.

Fig. 20 shows the microstructure of a compact pressed at 25 tsi and placed in the furnace at 1400°C and sintered for 24 hr at that temperature, while Fig. 21 shows the microstructure of a compact pressed at 25 tsi and placed in the furnace at 800°C and given a slow heating rate from 800° to 1400°C before the final sinter at that temperature. A comparison of the two figures shows clearly that the use of a slow heating rate preceding the high temperature sinter results in both fewer and smaller pores. This in turn, is reflected in a higher density for this type of treatment.

### Summary

1—Data are presented to show the influence of various pressing and sintering conditions upon the

permeability, density, and percentage of pores connected to the surface of Fe-Co powder compacts. This data has led to a study of the effect of evolved gases on the sintering process and to a successful minimization of the influence of such gases.

2—It has been shown that a density study does not always afford a reliable means of following the sintering process in powder compacts. On the other hand, liquid permeability measurements have indicated changes occurring in the sintering process not revealed by density measurements. Permeability has been shown to be a fairly good measure of the relative pore sizes of powder compacts, as well as the degree to which these pores are interconnected. While a metallographic study offers a reliable check on the relative pore sizes, it is lacking in that it does not show the degree of interconnection of the pores. The pore volume measurements introduced here offer a new method of determining the percentage of the total pores in a compact that are actually connected to the surface.

3—The experiments performed indicate that the role of gases during the initial stages of the sintering

process have an important influence upon the final density of compacts sintered to achieve theoretical density. In this connection, high compacting pressures, rapid heating rates, and high sintering temperatures exaggerate the effect of evolved gases and promote the formation of large initial pores which are eliminated during continued sintering only with difficulty.

4—A density close to that for the fused alloy (97.5 pct) has been obtained for 50 pct Fe-50 pct Co powder compacts by providing for the escape of liberated gases before appreciable sintering has occurred.

5—The results of this investigation should prove of interest to powder metallurgists concerned with the production of very high density materials or with the production of parts having a controlled porosity, such as bearings and filters.

#### Acknowledgments

The authors wish to express their appreciation to the U. S. Signal Corps for the supply of materials and equipment used in this investigation. For the vacuum fusion and other chemical analyses, the authors are grateful to the Allegheny Ludlum Steel Corp. The authors are especially indebted to W. C. Walker, of the Department of Chemistry, Lehigh University, for outlining the method for making the pore volume measurements. Finally, gratitude is expressed to the E. I. du Pont de Nemours and Co., who made this investigation possible by their grant of a fellowship in metallurgical engineering.

# Constitution and Precipitation-Hardening Properties of Copper-Rich Copper-Tin-Beryllium Alloys

by R. A. Cresswell and J. W. Cuthbertson

THE constitution of Cu-rich alloys with 1.5 to 13.5 pct Sn and 0.25 to 3.0 pct Be and the precipitation-hardening characteristics of alloys with 1.5 to 13.5 pct Sn and 0.25 to 1.0 pct Be have been examined.

The hardness and tensile strength of the alloys examined increase markedly after solution treatment at 700°C followed by heat treatment at temperatures between 200° and 450°C. By a combination of cold work and heat treatment, hardness values similar to those exhibited by commercial Be-Cu alloys containing 2.25 pct Be can be obtained with ternary alloys containing 9 pct Sn and 0.75 pct Be and containing 10 pct Sn and 0.5 pct Be. Marked hardening effects occur with alloys containing even less beryllium. By heat treatment alone, a hardness value of 310 diamond pyramid hardness can be obtained from an alloy containing 10 pct Sn and 0.75 pct Be. Preliminary tensile tests have shown that an ultimate tensile strength of 110,000 psi with an elongation of 23 pct is obtainable by precipitation hardening an alloy with 8 pct Sn and 0.75 pct Be.

The precipitation-hardening process has been followed microscopically for certain alloys and the inference is that, while the initial hardening effect is probably explained by the precipitation of the  $\beta'$  phase of the Cu-Be system, further hardening, proceeding at a much slower rate, also occurs, apparently as a result of precipitation of phases of the Cu-Sn system, particularly precipitation of the  $\epsilon$  phase at temperatures below 350°. The presence of the  $\epsilon$  phase of the Cu-Sn system in certain alloys at temperatures below 350°C has been confirmed.

Tin-bronzes are widely used in engineering applications where a combination of high strength and good resistance to corrosion is wanted. The maximum strength is induced in these alloys by cold working, and it would be an advantage for many purposes if high strength could be achieved alternatively by an age-hardening process. While Cu-Sn alloys have a good fatigue resistance they can be surpassed in this respect by Cu-Be, but the use of the latter alloy is limited by its high cost. If, by adding beryllium to tin-bronze, the properties of the respective binary alloys could to some extent be combined, a most attractive alloy should result.

As pointed out by Raynor,<sup>1</sup> beryllium is on the borderline of the zone of favorable size factors for copper, and the solid solubility of beryllium in copper is consequently much more restricted than if the size factor were strongly favorable. The size factor is sufficiently favorable, however, to permit an increase in solid solubility with rise in temperature, and there is thus a composition range in which Cu-

Be alloys are susceptible to hardening by precipitation heat treatment. Although the  $\alpha$  phase of the Cu-Sn system is similarly susceptible to precipitation treatment, the time necessary to establish equilibrium in commercial alloys of this type is usually so great that age hardening becomes impracticable.

The addition of beryllium to Cu-Sn alloys would appear to offer a means of conferring on the latter useful age-hardening properties. Masing and Dahl<sup>2</sup> and others have, in fact, shown that the addition of beryllium to Cu-Sn  $\alpha$  solid solutions renders these alloys susceptible to precipitation hardening and after such hardening confers on them an encouraging improvement in physical properties. If this improvement could be achieved by the addition of substantially smaller amounts of beryllium than are customarily found in binary Cu-Be alloys, the ternary alloys should possess economic advantages which might make them more attractive than the binary alloy for some applications.

## Binary Systems

**Copper-Tin:** The constitution of these alloys is now reasonably well known and is summarized in the equilibrium diagram published by Raynor.<sup>3</sup>

The following observations, due to Raynor,<sup>1</sup> on the structure of those phases of the Cu-Sn system that are likely to be found in the ternary alloy system will facilitate the subsequent discussion on the examination of that system. The  $\beta$  phase is an electron compound at the electron-atom ratio 3:2 and has a body-centered cubic crystal structure. This phase is stable only down to 586°C, at which temperature it decomposes eutectoidally into the  $\alpha$  and  $\gamma$  phases. The  $\gamma$  phase has a structure that is also based on the cubic system. This phase is stable down to 520°C, at which temperature it decomposes eutectoidally into the  $\alpha$  and  $\delta$  phases. The  $\delta$  phase is an electron compound ( $\text{Cu}_{21}\text{Sn}_8$ ) which has a crystal structure analogous to that of  $\gamma$  brass. This phase is stable from 590° to 350°C; on prolonged annealing at the latter temperature it breaks down into a mixture of the  $\alpha$  and  $\epsilon$  phases. The  $\epsilon$  phase is an electron compound ( $\text{Cu}_3\text{Sn}$ ) having the electron-atom ratio 7:4. Its structure may be regarded as a superlattice based on the close-packed hexagonal system. This phase is stable from 676°C to room temperature.

The primary solid solubility of tin in copper increases to a maximum of 15.8 pct as the temperature falls from that of the peritectic reaction to 586°C. The solid solubility remains constant from 586° to 520°C. At lower temperatures the solubility decreases progressively. Below 350°C the fall in solubility is pronounced and is associated with the precipitation of the  $\epsilon$  phase. This precipitation is very sluggish and does not normally occur under service conditions.

**Copper-Beryllium:** The Cu-Be system has been investigated by Borchers<sup>4</sup> and others. Raynor<sup>5</sup> summarized the present state of information on it.

R. A. CRESSWELL is Research Metallurgist and J. W. CUTHBERTSON is Assistant Director of Research, Tin Research Institute, Perivale, Greenford, Middlesex, England.

Discussion on this paper, TP 3134E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 10, 1951. Detroit Meeting, October 1951.

The solid solubility of beryllium in copper does not exceed 2.1 pct. Beyond the  $\alpha$  range increase in beryllium content up to about 12 pct leads to the appearance of first the  $\beta$  phase and subsequently the  $\beta'$  phase (the latter phase is designated  $\gamma$  by Borchers). The  $\beta$  and  $\beta'$  phases both have body-centered cubic structures, the former being disordered and the latter ordered. Hume-Rothery, Reynolds, and Raynor<sup>9</sup> consider that both of these phases are probably derived from the same 3:2 electron compound. The  $\beta$  phase decomposes eutectoidally at 575°C giving the  $\alpha$  and  $\beta'$  phases.

**Tin-Beryllium:** So far as could be traced no information has been published on the Sn-Be system. Raynor considers that the size factor relationships in this case are unfavorable.

### Ternary System

The first work carried out on the Cu-Sn-Be system was done by Masing and Dahl in 1929.<sup>2</sup> They determined the limits of the  $\alpha$  phase at 750°C and examined the possibilities of precipitation hardening in these alloys. Rowland and Upthegrove<sup>7</sup> have pointed out, however, that owing to insufficient annealing the specimens on which Masing and Dahl based their conclusions were not in equilibrium and the results of the latter's findings in regard to the constitution diagram are thus open to criticism. Rowland and Upthegrove have examined the structure of Cu-Sn-Be alloys containing up to 1 pct Be. They have not, however, studied the age-hardening properties of these alloys in detail, and since in their investigation they used the older type of Cu-Sn constitution diagram based on the work of Heycock and Neville, they appear to have overlooked the transformation of the  $\delta$  phase of that system at approximately 350°C. In the light of later work on the Cu-Sn system it would seem the  $\beta'$ ,  $\beta + \gamma$ , and  $\gamma$  fields reported by Rowland and Upthegrove can almost certainly be identified with one continuous  $\gamma$  field.

### Scope of Present Investigation

In planning this investigation the general form of Rowland and Upthegrove's diagram and the results of their thermal analyses were accepted, and it was decided only to consider those sections of the system which, in view of the information that has become available since these investigators published their results, might justify re-examination. In view of these uncertainties it was deemed advisable to redetermine certain parts of the ternary diagram in order to settle what phases are most likely to be precipitated on heat treatment of alloys near the  $\alpha$  phase boundary, i.e., alloys in which the maximum degree of precipitation hardening is to be expected.

The boundaries of selected isothermal sections of the ternary model were determined by microscopical examination of annealed and quenched specimens. The effects of heat treatment on selected alloys were examined and a limited study was made of the mechanical properties of these alloys.

### Experimental Procedure

In all, 68 different alloys were prepared. Of these 58 were made from electrolytic copper, Chempur tin, and a Cu-Be master alloy containing 4 pct Be. The remaining 10 alloys, which were used to settle any doubtful questions in the constitution work, were made from raw materials that were spectrographically standardized and of very high purity.

The analyses of the copper, tin, and master alloy

Table I. Analyses of Raw Materials

| Material                 | Impurity Content                                                             |              |               |               |
|--------------------------|------------------------------------------------------------------------------|--------------|---------------|---------------|
| Copper.....              | Fe 0.005 pct                                                                 | As 0.001 pct | Cd 0.001 pct  |               |

|                          | Pb 0.0027 pct                                                                | Sb 0.003 pct | Bi 0.0006 pct |               |
|                          | Cu 0.0005 pct                                                                | As nil.      |               |               |
| Cu-Be Master Alloy ..... | 0.3 pct total impurity, mainly Fe, Al and Si in approximately equal amounts. |              |               |               |

are given in Table I, and the tin and beryllium contents of the prepared alloys are reported in Table II. All samples were analyzed for tin content by precipitation with tannin and for beryllium content by precipitation with 8-hydroxy quinoline and ignition to oxide, traces of iron and aluminium being removed first. The impurity content of selected alloys was determined and the total amount of impurity found did not exceed 0.1 pct. The average silicon content was 0.03 to 0.05 pct and traces of iron and aluminium were detected.

In preparing the majority of the alloys for the constitution work, the metals were melted in a salamander crucible heated in an electric furnace of the silicon-carbide resistor type. During melting, a stream of oxygen-free nitrogen was passed through the furnace and melting was carried out as quickly as possible. The usual procedure in making up alloys of low beryllium content was first to melt the copper and bring its temperature rapidly to about 1300°C and then to add the tin and master alloy which were first preheated. The normal casting temperature was 1150°C. Before casting, the melts were stirred with a carbon rod and casting was effected through a preheated tundish into a chill mold  $\frac{3}{4}$  in. in diam preheated to 200°C. In the case of the alloys of higher beryllium content, the total charge was placed in the crucible at the outset and melting and casting were carried out as before. The usual weight of the melts prepared in the electric furnace was 250 g. Experience indicated that provided the melting was done quickly there was no significant increase in the silicon content of alloys prepared in this way. With prolonged heating the silicon in the alloy may increase as a result of reduction of the silica in the crucible by the beryllium in the melt.

Larger melts were required for studying precipitation hardening and the mechanical properties of the alloys, and these were prepared as follows. Melting was done in a gas-fired injector furnace. The

copper was melted under an oxidizing flux consisting of equal parts of cupric oxide, borax, and sand, and was raised to a temperature of 1250° to 1300°C. The flux was thickened with sand and removed. The copper was deoxidized with 15 pct phosphor-copper and the Sn and Cu-Be alloy were added in that order. The melts were poured at 1150°C into a cast iron mold measuring 10x2x1½ in. preheated at 150°C. Slow pouring was insured by the use of a tundish having an outlet orifice ⅛ in. in diam. The weight of the castings made in this way was approximately 1200 g. Before use, these castings were annealed at 700°C for 15 hr. While these samples were prepared primarily for the purposes mentioned above, melts thus made that on analysis were found to be substantially free from phosphorus were also used to provide additional data on alloy constitution, particularly in the higher tin regions.

#### Preparation of Microspecimens

The cast alloys were annealed for 2 hr at 700°C, hammered while hot, reannealed at 700°C for 16 hr,

and water quenched. Drillings for chemical analysis were taken from the bottom of each ingot and the specimens for microscopic examination were cut from the portion just above. No variation in composition along the lengths of the castings was detectable, and it is considered that the chemical analyses correspond very closely with that of the microspecimens taken from adjacent parts of the castings. Six batches of microspecimens were cut from castings of the desired compositions, and all of the specimens were annealed at 700°C for 96 hr. At the end of this time the first batch of specimens was withdrawn and water quenched. The temperature of the annealing furnace was then slowly lowered to 600°C and maintained at this temperature for a further 96 hr, following which the second batch of specimens was water quenched. This procedure was repeated, with progressive decrease in the intermediate cooling rate, at 580°, 500°, and 400°C. The final batch of specimens was held at 300°C for 168 hr before quenching. On examination of the samples in this batch it was found that soaking for 168 hr was not

## Legend

sufficient to establish equilibrium in all of the alloys, and selected alloys near phase boundaries were therefore reannealed for a further 60 days to insure that equilibrium was established.

The microsections were prepared by hand polishing on Selvyt cloth moistened with Silvo metal polish and soap, and were etched in alcoholic ferric chloride or preferably in alkaline cuprammonium chloride. The latter etchant was found to give excellent phase differentiation in the majority of the three-phase alloys.

## Results of the Constitution Investigation

The ternary isothermals at 700°, 600°, 580°, 500°, 400°, and 300°C are shown in Figs. 1 to 6.\* For

purposes of comparison some of the points on the phase boundaries of Rowland and Upthegrove's diagram have been included.

**Sections at 700° and 600°C:** It is confirmed, Figs. 1 and 2, that the  $\beta$  phases of the Cu-Sn and Cu-Be systems form a continuous series of solid solutions and that at these temperatures alloys in the copper corner of the diagram consist of  $\alpha$ , or  $\alpha + \beta$ . The  $\beta$  phase is retained by quenching and is easily recognizable as white island in the darker  $\alpha$  matrix. The phase boundaries at these temperatures are in close agreement with those of Rowland and Upthegrove.

\* In Figs. 1 to 6 the abbreviation CuSn, etc., merely indicates the constituent metals and not the compositions of the respective phases.

**Section at 580°C:** Owing to the transformation at 586°C of the  $\beta$  phase of the Cu-Sn system into  $\alpha + \gamma$ , this section, Fig. 3, shows a marked change from the one at 600°C. Pseudobinary systems are formed between the  $\alpha$  and the  $\beta'$  phases of the Cu-Be system and between the  $\gamma$  phase of the Cu-Sn system and the  $\beta'$  phase of the Cu-Be system. One three-phase field appears between the  $\alpha$ ,  $\beta$ , and  $\beta'$  phases of the Cu-Be system and another between the  $\alpha$ ,  $\beta'$  CuBe, and  $\gamma$  phase of the Cu-Sn system. In the  $\alpha + \beta'$  CuBe +  $\gamma$  Cu-Sn field, the islands that were originally  $\beta$  now consist of  $\gamma$  Cu-Sn and/or  $\beta'$  CuBe and  $\alpha$ , and have become coarse in structure. The  $\gamma$  Cu-Sn phase is light gray in color and similar in form to the  $\beta$  phase of the Cu-Sn system. The  $\beta'$  CuBe phase, designated  $\theta$  by Rowland and Upthegrove, is readily recognized by its white color and acicular form. Fig. 7 shows the equilibrium structure of an alloy containing approximately 2.5 pct Sn and 2 pct Be and reveals needles of CuBe and islands of Cu-Sn in a matrix of  $\alpha$ .

**Sections at 500° and 400°C:** In these sections, Figs. 4 and 5, the  $\gamma$  phase of the Cu-Sn system is no longer present having undergone a eutectoid inversion into  $\alpha + \delta$ . At these lower temperatures the  $\alpha$  solid solubility is reduced and  $\beta'$  CuBe or  $\delta$  Cu-Sn (or both) phases precipitate from the  $\alpha$ . The  $\delta$  phase of the Cu-Sn system is precipitated from the  $\alpha$  at the grain boundaries and within the grains themselves and is readily distinguished by its bluish-gray color. The  $\beta$  phase no longer exists and is replaced by a more complex structure consisting of  $\alpha$  and either  $\beta'$  CuBe or  $\delta$  Cu-Sn, or both, depending on the composition (see Figs. 8 to 10).

The range of  $\alpha$  solid solubility at 500°C was found

Fig. 13—Hardness-time curves of rolled specimens annealed at 700°C, water quenched, and aged at 250°C.

to be more restricted than is indicated in Rowland and Upthegrove.

**Section at 300°C:** Only a trace of the  $\delta$  phase was observed in specimens annealed at 300°C for 8 weeks, Fig. 6: the  $\delta$  phase had practically all decomposed to give  $\alpha$  and  $\epsilon$ , Figs. 11 and 12. Some  $\epsilon$  is also precipitated from the  $\alpha$  in form of very small gray particles, some of which are barely resolved at a magnification of 2000. X-ray examination confirmed the existence of this phase in alloys in equilibrium but failed to detect its presence in alloys annealed for only two weeks.

The restriction in  $\alpha$  solid solubility at this temperature was found to be very marked, and diverged considerably from that observed by Rowland and Upthegrove.

## General Discussion

All phase boundaries were found to shift toward lower tin contents with increase in beryllium content. Also, the  $\alpha$  field of the ternary system was found to decrease in area with decrease in temperature below 600°C. This decrease becomes marked at temperatures below the  $\gamma \rightarrow \alpha + \delta$  transformation of the Cu-Sn system and is still more marked below the temperature of the  $\delta \rightarrow \alpha + \epsilon$  transformation of the Cu-Sn system. This decrease in solubility accounts for the susceptibility to precipitation hardening in certain alloys of the ternary system noted by Masing and Dahl. The effect of composition and temperature on the limits of  $\alpha$  solid solubility can be appreciated from the figures given in Table III.

## Precipitation Hardening of Cu-Sn-Be Alloys

Masing and Dahl showed that Cu-Sn-Be alloys of suitable composition could be heat treated in the same way as binary Cu-Be alloys and demonstrated that the hardness of ternary alloys could be very considerably increased by aging after solution treatment. Further, aging was shown to be possible at temperatures below the recrystallization temperature, and the effect of cold working and precipitation hardening could therefore be superimposed.

The majority of Masing and Dahl's alloys contained 1.25 pct Be, or more. As such alloys would offer little economic advantage over the standard binary alloy containing around 2 pct Be, it was decided to investigate alloys of lower beryllium content. The alloys investigated had nominal contents of 2.0 to 13.5 pct Sn and 0.25 to 1.0 pct Be.

Rolled specimens were mainly used for the study of precipitation hardening. The melting procedure adopted in making ingots for this part of the work has already been described. After annealing the ingots at 700°C for 15 hr attempts were then made to hot roll them, but serious cracking occurred with all compositions. Cold rolling was therefore substituted and a number of ingots were successfully cold rolled down to a thickness of 0.1 in. Some ingots cracked badly in the early stages of rolling, especially those of alloys containing a large amount of a second phase. By adopting certain expedients the

Table III. Limiting Tin Content of  $\alpha$  Solid Solutions

| Temperature, °C | Tin, Pct       |               |             |
|-----------------|----------------|---------------|-------------|
|                 | At 0.25 Pct Be | At 0.5 Pct Be | At 1 Pct Be |
| 700             | 12.7           | 9.6           | 5.4         |

Fig. 16—Hardness-time curves of rolled specimens annealed at 700°C, water quenched, and aged at 400°C.

tendency to cracking was reduced and in many cases cracking was completely eliminated.

The procedure finally adopted was as follows: The annealed ingots were cold rolled to a reduction of 30 to 40 pct in several passes; they were then annealed for 15 min and again cold rolled as before. The whole procedure was repeated until a thickness of 0.1 in. was attained. In this way alloys Nos. 6, 8, 9, 16, 20, 21, 41, 49, 50, 55, 56, 57, 61, 64, and 68 selected from the list given in Table II were successfully worked. For comparison, a binary tin-bronze containing 14.55 pct Sn was also prepared, and no trouble was experienced in working this alloy. The remaining alloys selected, namely, Nos. 62, 63, 65, 66, and 67, contained a large amount of a second phase in addition to the  $\alpha$  constituent, and these alloys cracked severely on cold working.

All specimens were subjected to a solution heat treatment at 700°C before aging. This temperature is below the solidus for all of the alloys examined. Equilibrium was established in worked alloys after annealing at this temperature for 16 hr. Aging after solution treatment was carried out at 250°, 300°, 350°, 400°, and 450°C, the times of treatment being 0.5, 1, 2, 4, 8, 16, 32, and 64 hr: In addition, at 250°C the effect of prolonged aging for 128 and 256 hr was studied. Some alloys containing low amounts of tin and beryllium were also examined after aging at only 200°C.

**Effect of Aging on Hardness:** Hardness tests were made with a Vickers machine using a load of 50 kg and a time of application of 15 sec. At least three impressions were made for each test. The results obtained on rolled material were consistent, but

there was some scatter in the hardness readings for as-cast samples.

The relationship between hardness and time of aging is shown in Figs. 13 to 16. For all ternary alloys aging at 250°C causes a rapid increase in hardness during the first hour, after which the hardness increases at a steady rate that is almost directly proportional to the logarithm of the time. The latter increase continues up to 256 hr. After 256 hr alloy No. 57 had a hardness of 310, which is the maximum figure recorded for any preannealed alloy. On aging at 300°C, the increase in hardening during the first hour is greater than at 250°C: On further aging at 300°C, the hardness remains fairly constant except in the case of alloys low in tin and beryllium for which the hardness increases progressively.

On aging at 350°C, the hardness of alloys containing 0.75 pct Be reaches a maximum after about 1 hr and thereafter remains substantially constant. Alloys of lower beryllium content continue to increase in hardness after 1 hr, but less markedly than when aged at 250° and at 350°C. On aging at 400°C and at 450°C, the hardness after the first hour of alloys with 0.5 to 0.75 pct Be diminishes with time; alloys with 0.25 pct Be show a progressive increase in hardness, as in the lower temperature treatments.

The extent to which hardness increases on aging appears to be determined almost entirely by the beryllium content of the alloys. Increase in the tin content of the alloys raises the general level of the hardness-aging time curves but does not significantly affect age hardening. Except in the case of alloys high in tin and beryllium, where the maximum hardness is reached after aging at 400° to 450°C, the remaining alloys attain their greatest hardness after aging at 250°C for 256 hr.

It was observed that many of the alloys examined could be cold worked in the solution-treated condition and the effect of age hardening superimposed on work hardening was next investigated. Figs. 17

Fig. 17—Hardness-time curves for alloy No. 56 quenched from 700°C, cold rolled, and aged at 250°C.

Fig. 21 (right) — Effect of aging temperature on the hardness, tensile strength, and elongation of rolled alloys.

to 20 show the hardness-time curves for two selected alloys solution treated and subjected to varying degrees of cold working followed by aging at 250° or 300°C. These alloys showed an increase in hardness of about 170 as a result of heavy cold working and on aging at 250°C showed a further rapid increase in hardness during the first hour followed by a slower progressive hardening which continued up to 64 hr without any sign of diminishing.

Table IV compares the maximum hardness values obtained for Cu-Sn-Be alloys with the hardness of commercial Cu-Be alloy containing 2.25 pct Be. It is apparent that although the hardness of the ternary alloys when aged from the solution-treated condition does not approach that of the binary Cu-Be alloy, the hardness of the ternary alloys can, if their beryllium content approaches 0.75 pct, be made equal to that of the binary alloy by a combination of cold work and precipitation heat treatment.

Where composition permits a direct comparison to be made, it is noteworthy that the initial and final hardness figures obtained in this work are considerably higher than the corresponding figures reported by Masing and Dahl.

The effects of heat treatment on a few as-cast alloys were examined and were found to be much the same as in the case of the rolled alloys, but the cast alloys gave somewhat lower initial and final hardness figures. The maximum hardness developed at a given temperature was reached in about the same time for both cast and rolled materials. Those alloys which failed to roll satisfactorily, owing to the high proportion of second phase present therein, all

reached high hardness values on heat treatment in the as-cast condition.

**Effect of Aging on Tensile Strength and Elongation:** Tensile tests were carried out on flat specimens 0.1 in. thick having a gage length of 2 in. Specimens were tested after solution treatment at 700°C followed by aging for 1 hr at 250°, 300°, 350°, 400°, and 450°C, respectively. The results obtained are shown in Fig. 21, which also includes comparison curves showing the effect of aging temperature on hardness. For single-phase alloys there is a reasonable correspondence between the effects of aging on hardness and on tensile properties. Perhaps the only significant divergence between the two properties is the lack of any marked increase in ductility in those cases where an increase in aging temperature has led to a fall in hardness. The best tensile properties were revealed by alloy No. 41 (8 pct Sn, 0.75 pct Be, nominal) which, after aging at 300°C, gave a tensile strength of 110,000 psi and an elongation of 23 pct. A similar tensile strength can be induced in high tin-binary bronze by cold working, but the accompanying elongation is much lower than that for the ternary alloy.

**Effect of Aging on Electrical Resistivity:** Resistivity-aging time curves are given in Figs. 22 to 25. There is little correlation between the effect of heat treatment on electrical resistivity and its effect on hardness. On aging at 250° and at 300°C the electrical resistivity of all of the alloys rises slightly at first and then falls continuously. On aging at higher temperatures there is a continuous fall in resistivity. An increase in electrical resistivity frequently occurs during the early stages of precipitation hardening, and the maxima in the hardness and electrical resistivity curves do not necessarily coincide. The maximum resistivity was developed in these alloys before precipitation could be detected under the microscope; this is usual in precipitation hardening.

**Effect of Aging on Microstructure:** After annealing and quenching, alloys outside the  $\alpha$  phase boundary at 700°C were duplex in structure, the second phase being retained  $\beta$ ; the presence of beryllium aids the retention of  $\beta$ .

The metallographic changes during aging were closely followed for alloys containing 10 pct Sn and 0.75 pct Be and those containing 11 pct Sn and 0.5 pct Be (nominal compositions). At all aging tem-

Table IV. Comparative Hardness Values for Cu-Sn-Be and Cu-Be Alloys

| Alloy                                   | Vickers Hardness Number |             |              |                                 |

temperatures the  $\beta$  phase commences to decompose in the first 30 min. According to the equilibrium diagram, the  $\beta$  phase should be converted to  $\alpha + \delta$  above 350°C and to  $\alpha + \epsilon$  below 350°C; generally speaking, it is impossible to resolve the precipitated individual phases under the microscope. Precipitation occurs in the  $\alpha$  phase of all of the alloys examined and takes place in three stages. In the first stage there is a thickening of the grain boundaries leading to a definite precipitate on further aging. In the next stage martensitic markings develop within the  $\alpha$  grains and increase in intensity as aging proceeds. The third stage, which at 400°C is reached after aging for 4 to 8 hr, corresponds to the disappearance of the martensitic markings and the appearance of precipitated particles within the  $\alpha$  grains, Fig. 26.

Grain boundary precipitation is most marked in alloys that are originally duplex in structure. Precipitation commences from the  $\beta$  areas and the precipitated phase ultimately forms a continuous network surrounding the  $\alpha$  grains, Fig. 27. The presence of this intergranular network is thought to account

for the lower tensile strength of high tin as compared with that of lower tin alloys containing a high percentage of beryllium, see Fig. 21. At higher aging temperatures there is a tendency for the grain-boundary precipitate to ball up and form a discontinuous chain of particles, Fig. 28.

In alloys that are three phase after aging it is impossible to distinguish the two separate phases precipitating in the  $\alpha$  as the structures are so complex, Fig. 29. In these alloys the structure probably consists of an intimate mixture of fine particles of  $\beta'$  CuBe and  $\delta$  or  $\epsilon$  embedded in a matrix of  $\alpha$ . It is only possible in two-phase alloys to obtain structures that can be correlated with the equilibrium diagram by aging the alloys at high temperatures for a long time. Typical structures obtained in this way are shown in Figs. 30 and 31.

The course of precipitation in the low tin, low beryllium alloys is marked at the outset by a thickening of the  $\alpha$  grain boundaries and the appearance of lines of precipitation along lattice planes within the  $\alpha$  crystals, Fig. 32. On further aging, the lines

of precipitation along the planes within the  $\alpha$  grains become more numerous and it is easy to follow this change of direction at the  $\alpha$  grain boundaries and at twin discontinuities, Fig. 33. On still further prolonging the time of aging, the grain boundaries and lines within the grains become thicker and ultimately it is possible to resolve the latter as particles of the precipitated second phase, Fig. 34.

#### Effect of Aging

The fall in resistivity which occurs on aging Cu-Sn-Be alloys precedes slightly the onset of grain-boundary precipitation. This is in accordance with the hypothesis that maximum lattice strain is reached before visible precipitation occurs. It is somewhat surprising that the appearance of resolvable particles in the  $\alpha$  is not accompanied by a fall in hardness, except for aging at 400° and at 450°C, as in age-hardening systems the hardness generally reaches a maximum before visible precipitation occurs. It is possible that there is some undetected heterogeneity in the  $\alpha$  phase of these ternary alloys and that the softening in certain areas, which theoretically should occur when visible particles form, is offset by hardening in other areas in which precipitation is less advanced. Such heterogeneity might arise through differential stress resulting from non-uniform rolling. However, it is tentatively suggested that in the case of three-phase alloys, which have been annealed at temperatures not exceeding 350°C,

Fig. 34—Structure of alloy No. 27, 5 pct Sn-0.5 pct Be, after aging at 250°C for 32 hr. X2000.

the initial hardening and the first visible precipitation is attributable to precipitation of the  $\beta'$  phase of the Cu-Be system and that subsequent softening is overshadowed by slow, progressive hardening resulting from the sluggish precipitation of the  $\epsilon$  phase.

#### Summary and Conclusions

Isothermal sections of the ternary Cu-Sn-Be system have been determined by microscopic methods for alloys in equilibrium at 700°, 600°, 580°, 500°, 400°, and 300°C and for the composition range 0.25 to 3.0 pct Be and 1.5 to 13.5 pct Sn. The decrease in the limit of  $\alpha$  solid solubility with fall in temperature is found to be more marked than is indicated by the work of previous investigators, particularly at temperatures below 350°C, where the field is restricted by the eutectoid transformation of the Cu-Sn system. The presence of the  $\epsilon$  phase of the Cu-Sn system in specimens that had been annealed at 300°C for 8 weeks was confirmed by X-ray examination.

Alloys containing 0.25 to 0.75 pct Be and 2.0 to 13.5 pct Sn have been shown to possess age-hardening properties. The extent of precipitation hardening obtainable depends primarily on the beryllium content of the alloy. After appropriate aging of rolled and solution-treated material, the maximum hardness is obtained with a nominal composition of 10 pct Sn, 0.75 pct Be. For the same pretreatment, the maximum tensile strength is obtained with a nominal composition of 8 pct Sn, 0.75 pct Be; this alloy can show an ultimate tensile strength of 110,000 psi with an elongation of 23 pct on 2 in. The hardness of the ternary alloys, aged from the solution-treated condition, does not reach that of heat-treated binary Be-Cu alloys with around 2 pct Be, but by cold working solution-treated alloys prior to aging, hardness figures comparable with those exhibited by commercial Cu-Be alloys can be obtained from ternary alloys of suitable composition.

Annealed alloys containing a large amount of second phase tend to crack on cold rolling. These alloys can be heat treated, however, to give high hardness values, a hardness of 260 being attainable for alloys of high tin and high beryllium content.

The constitution changes taking place during precipitation heat treatment have been examined. It is suggested that, on aging three-phase alloys below 350°C, the observed initial hardening is attributable

to precipitation of the  $\beta'$  phase of the Cu-Be system and that the subsequent hardening is explained by slow precipitation of the  $\epsilon$  phase of the Cu-Sn system.

In view of the high cost of beryllium, the fact that approximately the same properties can be obtained in a ternary alloy containing 0.75 pct Be as in a binary alloy containing 2.0 pct Be is noteworthy, and there seems no reason to believe that the cheaper alloy might not function satisfactorily in some of the applications where the binary alloy is now used.

### Acknowledgments

This research was carried out in the laboratories of the Tin Research Institute. The authors are indebted to the International Tin Research and Development Council for permission to publish this paper. Grateful acknowledgment is made for guidance given throughout the course of the work by D. Hanson and G. V. Raynor, of the Department of

Metallurgy, University of Birmingham, England, the former to whom thanks are also due for carrying out the X-ray examination mentioned in the paper, and the latter for helpful advice and criticism.

### Technical Note

## Lattice Parameter of InSb

by T. S. Liu and E. A. Peretti

**A**LITERATURE survey of the In-Sb system, which was made before a study of the binary diagram was undertaken, revealed that the intermediate phase InSb existed and that its crystal structure is face-centered cubic of the zinc blend type. In 1929 Goldschmidt<sup>1</sup> determined the lattice constant for InSb and obtained a value of 6.452 Å. A more recent value, 6.461 Å was reported by Iandelli<sup>2</sup> in 1941. The purity of the indium used was not very high, however. The indium used by Iandelli contained 2 pct Ge. In view of this fact it was decided to remeasure the lattice parameter using high-purity indium (99.97+ pct In) and spectrographically standardized antimony of the highest purity available (99.91 pct Sb).

Specimens corresponding to the InSb composition were made by carefully weighing the ingredients on an analytical balance and heating them in vacuo in a quartz tube at 700°C. As melting losses were negligible, the alloys were not analyzed chemically, but the intended analysis was taken as being accu-

rate. Powder samples were prepared by either filing or crushing of the brittle alloy, followed by screening at 325 mesh. The powders were then annealed at 400°C in evacuated capsules for about an hour.

X-ray photographs were taken with a Debye and a back-reflection focusing camera, using characteristic cobalt  $K_\alpha$  radiation. Lattice parameters were calculated by Cohen's<sup>3</sup> method. The results of a Debye pattern and of a back-reflection pattern at 25°C are given in Tables I and II.

The lattice parameter at 25°C is 6.4760 Å.

# Creep Behavior of Zinc Modified by Copper in the Surface Layer

by Milton R. Pickus and Earl R. Parker

THE modern theories of creep<sup>1-4</sup> in general have been based upon the concept of generation and migration of dislocations, with the generation process normally assumed to be rate controlling. The theories are generally deficient in that they fail to take into account many factors that are known to influence creep. The influence of the state of the surface of the test specimen has been almost completely overlooked; yet the present report shows that the nature of the surface may, in certain cases, govern the creep characteristics of a specimen.

In the period since Taylor<sup>5</sup> applied the concept of dislocations to a study of metals, a school of thought has developed that closely relates the plastic deformation of metals to the generation and migration of dislocations through the crystal lattice. It might be expected that the thermal energy required for the generation of a dislocation would be different from that for migration of the dislocation through the lattice. Furthermore, the activation energy for generation would be expected to vary for different parts of the solid metal. It has been predicted that dislocations would be generated most easily at external surfaces, but could also be activated at certain internal surfaces such as grain or phase boundaries. Within the body of the metal a range of values for the activation energy might be expected because of different degrees of disorder at such regions as grain boundaries, impurities, and second-phase particles. The particular value of the activation energy that was rate determining could then depend on the specific conditions of a test. If, for example, the surface atoms were by some means constrained, the generation of dislocations in the body of the metal might become the important factor. On the other hand, other conditions may favor generation at the surface. It is possible then that the creep behavior may not be completely determined by the inherent properties of the metal. Even the environment in which a test is carried out could have a significant effect. In fact it is conceivable that in order to obtain the maximum creep resistance from a given alloy, the surface atoms must be so constrained that the activation energy for generating dislocations on the surface is at least equal to that required for generation in the body of the metal. On the basis of such considerations, and in view of the limited number of publications discussing this subject, it seemed that an investigation of the influence of the state of the surface on creep might yield information of both theoretical and engineering interest.

Experiments on single crystals, demonstrating a variation in the mechanical properties due to alterations in the surface layer, have been reported by several investigators.<sup>6-13</sup> The results of these experiments have been briefly summarized;<sup>14</sup> consequently, the earlier work will not be reviewed here.

M. R. PICKUS and E. R. PARKER, Members AIME, are Research Metallurgist and Professor of Physical Metallurgy, respectively, University of California, Berkeley, Calif.

Discussion on this paper, TP 3122E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 10, 1951. Detroit Meeting, October 1951.

This paper represents part of the work done on a research program under the sponsorship of the Office of Naval Research.

As an example of these findings the observations of Cottrell and Gibbons may be cited. They reported the critical shear stress of a lightly oxidized cadmium single crystal is greater by a factor of  $2\frac{1}{2}$  than a specimen with a clean surface.

## Materials and Methods

Single crystals  $\frac{1}{2}$  in. in diam and 8 in. long were prepared from Horse Head Special zinc, melted under an atmosphere of helium in a large pyrex test tube, and drawn up into a long  $\frac{1}{2}$  in. diam pyrex tube by means of a vacuum pump. The cast zinc rods thus produced were cut into convenient lengths and sealed in evacuated pyrex tubes. Single crystals were grown by gradual solidification of the remelted rods. Cleaving the ends of the single crystal specimens chilled by liquid nitrogen proved a simple method for determining orientations from the exposed basal plane from the markings left on the cleaved surface that gave the slip directions with sufficient accuracy for the experimental work. The specimens chosen for the experiments were those having the angle between the basal plane and the specimen axis within the range of  $15^\circ$  to  $65^\circ$ .

Since zinc single crystals are quite delicate, it was necessary to devise an appropriate method of gripping the specimens in order to suspend them in the furnace and apply the load. Stainless steel collars were prepared having an inside taper, the smaller end of the taper being of such a size that the specimen could just pass through freely. The tapered hole did not extend the full length of the collar; a sufficient thickness of metal remained so that a hook could be attached to provide a means of applying the load and suspending the specimen. One of the collars was slipped over the upper end of a specimen which was supported vertically in a steel jig. The collar was then heated electrically until the end of the crystal melted and filled the collar with molten zinc. At this point the application of heat was discontinued, whereupon the molten zinc quickly solidified, due to the chilling effect of the jig. The specimen was then inverted and the second collar applied in a similar manner. The jig served several purposes: limiting the length of specimen that was melted, providing excellent alignment of the collars with respect to the specimen axis, and protecting the specimen from mechanical damage.

Once the specimen was suspended in the furnace and loaded, it was desired to accomplish the surface treatment with a minimum of disturbance of the specimen. Around the specimen was a long pyrex tube, the upper portion of which was approximately 1 in. in diam, and in it was a copper coil of such a diameter to fit snugly against the tube. A specimen, approximately  $\frac{1}{2}$  in. in diam and 4 in. long, was suspended by means of a stainless steel rod so that it hung within the copper coil. The lower portion of the glass tube was approximately  $\frac{1}{4}$  in. in diam, and passing through it was a  $5/32$  in. diam stainless steel rod which hung from the lower specimen collar. This portion of the glass tube and the stainless steel rod extended through the bottom of the furnace. A T-connector, with suitable packing, was attached to the lower end of the stainless rod to provide a water-

tight seal. A yoke, attached to this rod by a gimbal joint, was used to activate a dial gage and from which the load was suspended by a coil spring. Fig. 1 shows the main features of the assembly.

The furnace consisted of an insulated rectangular box with two nichrome heating elements and a small fan so disposed that a uniform temperature over the gage length of the specimen was obtained. Three thermocouples mounted on a dummy specimen, one at each end, and one at the center of the gage length, showed less than  $1^{\circ}\text{C}$  difference in temperature. Three specimens could be tested simultaneously. A pyrex panel mounted in one of the sides made it possible to observe the specimens.

The gage length consisted of the 4 in. length of crystal between the gripping collars. Overall extension was measured by means of a dial gage graduated in divisions corresponding to a plunger travel of 0.0001 in. The range of the gage was 0.4 in.

The method of achieving reproducible surface changes decided upon consisted in applying electrolytically a thin layer of copper. With respect to zinc, copper may be considered a thermally inactive metal in the sense that at  $200^{\circ}\text{C}$ , for example, the kinetic energy of the copper atoms is still far below that required to overcome the bonding energy that holds the copper atoms in their lattice positions, whereas zinc atoms, in view of the relatively low melting point of  $419^{\circ}\text{C}$ , have kinetic energies more nearly commensurate with the magnitude of the energy holding the zinc atoms together. From these considerations, it was supposed that under the influence of stress and temperature, dislocations could be generated much more easily in a surface layer consisting of zinc atoms than in one containing copper atoms, or for the case where dislocations were generated internally, their escape to the surface would be hampered by the layer of copper.

In order to accomplish the desired changes in the surface layer, procedures were required for cleaning the zinc surface prior to the electrodeposition of copper, and for removing the electrodeposited copper while the specimen was in the assembled apparatus. Fortunately it was found that both of these requirements were met by an anodic treatment of the specimen in an electrolyte consisting of a 10 pct aqueous solution of sodium cyanide, the copper coil (Fig. 1) serving as a cathode. During the development of the anodic treatment, an interesting relationship was observed between the applied voltage and current. Several discontinuities were found, the best cleaning being obtained just after the first. The current was not a single valued function of the voltage; the same current could be obtained at several different voltages, depending on which of the discontinuous curves was applicable. Although the values of the current and voltage at the discontinuities depended on the size of the specimen and the temperature, the cleaning procedure proved to be quite simple, since it was necessary only to apply approximately 4 v and watch the ammeter needle. With the cell filled with electrolyte and the electrical connections made, the current slowly rose to a maximum and then dropped sharply. After 10 or 15 sec at the lower current the specimen was found to be cleaned effectively.

If the specimen was to be copper plated, the sodium cyanide solution was drained off, the polarity of the electrodes reversed, and the cell filled with a copper-plating solution. The zinc specimen was plated at a current density of 0.10 amperes per sq

Fig. 1—Specimen assembly.

in. for 90 sec. Both the specimen and electrolyte were at room temperature during the plating. The composition of the plating bath was as follows: Copper cyanide, 22.5 g per liter; sodium cyanide, 33.8; sodium carbonate, 15. The average thickness of the copper layer deposited under these conditions is  $10^{-5}$  in. After plating, or cleaning if that was to be the final step, the cell was rinsed first with water and then with alcohol. Finally the specimen and cell were dried by the passage of a stream of air.

In order to determine the effects of the copper deposit, it was found necessary to employ a single specimen for a complete test involving alternate changes in the surface layer. This procedure had the advantage of reducing the number of variables, although it did require an interruption in the test. Earlier experiments had shown that despite the care employed in the preparation of the single crystals, they nevertheless differed from one another in that the same creep rates for different orientations could not be obtained by adjusting the load to provide the same shear stress in the direction of slip. For one thing the extension was by no means uniform over the 4 in. gage length. In this respect there was a variation from one specimen to another. In an extreme case the entire deformation was localized in a small portion of the specimen, which had the appearance of two substantially undeformed portions markedly offset from each other over the width of a narrow slip band. This of course means that measuring the overall extension of the 4 in. specimen can give only a fictitious strain rate, since the true gage length is indeterminate. However, the measurement of the overall extension served as a convenient means of observing changes in a particular specimen. A few of the specimens subjected to elevated temperature creep tests are shown in Fig. 2. It should also be mentioned in this connection that the loading of the specimens to obtain the desired creep rate proved to be quite a problem. In many cases only a small increment of load beyond that producing a very slow rate of secondary creep resulted in the sudden onset of the third stage, with

Fig. 2—Examples of unplated zinc single crystals tested in creep at elevated temperatures.

large extensions occurring in a relatively short time. In some instances this increment of load was supported by the specimen for several hours, the creep progressing at a slow steady rate; then the creep rate would rise sharply, producing such excessive extension the particular test had to be abandoned.

After the specimen assemblies were suspended in the furnace, the specimens were cleaned anodically in the sodium cyanide solution and then rinsed and dried. The furnace then was heated to a higher temperature than was to be used for the tests, and a period allowed for temperature stabilization with the object of minimizing any changes in the state of the specimens due to heating at the test temperature. The furnace was cooled and brought to equilibrium at the test temperature before the load was applied. After the secondary creep rate was determined, the furnace was cooled to room temperature, with the specimens still under load. They were again cleaned anodically in the sodium cyanide solution, after which they were copper plated in the manner already described. The furnace was reheated to the test temperature and the secondary creep rate for the copper-plated condition determined. As already mentioned, the copper layer was effectively removed by the anodic cleaning procedure. Thus several cycles of creep for each condition of the specimen surface could be observed.

This procedure was adopted after several unsuccessful modifications. It was thought that for tests at temperatures near 100°C hot solutions could be employed, thus eliminating the necessity for interrupting the test by cooling down the furnace. However, the anodic treatment in sodium cyanide solution was not controllable in hot solutions.

On the other hand, if the furnace was maintained at the test temperature, and the specimens momentarily chilled by filling the cells with cool liquid, an effect of the cooling on the creep rate was invariably observed. This effect was analogous to that obtained by adding an increment to the load. The

Fig. 3—Change in creep rate of a zinc single crystal produced by a thin copper plate. Test temperature, 100°C. Resolved shear stress, 31.5 psi.

creep rate increased rather sharply and the effect persisted for several hours.

Several tests were performed wherein during a period of steady creep no change was made other than to cool the furnace to room temperature, and then reheat it to the test temperature. In all cases the creep rate was unchanged by the slow cooling and heating cycle. It appeared, therefore, that in order for there to be an effect on the creep rate due to cooling the specimen, a temperature differential must be set up between the surface and interior of the specimen. The fact that no noticeable effect was introduced by gradual cooling was regarded as justification for the test procedure that was adopted.

In this manner the effect of copper in the surface layer on the secondary creep rate was studied at constant temperature and constant load. This was done for polycrystalline zinc and for single crystals. The temperature dependence at constant load of the secondary creep rate was also determined for both forms of zinc with and without the presence of an electrolytically deposited layer of copper.

The polycrystalline specimens were in the form of

Fig. 4—Change in creep rate of a zinc single crystal produced by a thin copper plate. Test temperature, 200°C. Resolved shear stress, 26.5 psi.

cast rods of chemically pure zinc. While the grain size of these specimens was somewhat coarse, a cross-section contained many grains so that a comparison between single crystal and polycrystalline zinc could be obtained. The polycrystalline specimens were 5½ in. long and ¼ in. in diam, with a 2 in. reduced section of 0.187 in. diam which served as the gage length.

### Experimental Results

In the course of the experimental work a large number of single crystals in a considerable range of orientations were tested. The results in all cases followed the same general pattern. The creep rate was sharply decreased by the presence of the thin copper layer. When the copper was removed, the creep rate increased to the value obtained for the unplated specimen. The effect of the copper was large, amounting in some cases to essentially a complete cessation of flow. In an extreme case when a test was carried to a point where the cross-sectional area was noticeably diminishing, the application of the copper deposit arrested the acceleration of creep rate.

The results of typical tests are shown graphically in Figs. 3 and 4. In Fig. 3 is recorded a test at 100°C showing the effect of a series of plating and deplating cycles. Even though necking had begun in the latter stages of the test, the effect of the copper was still definite. Fig. 4 shows the results of a similar test at 200°C.

Numerous tests on the polycrystalline specimens

Fig. 5—Composite plot of data from 18 tests designed to establish the temperature dependence of creep for polycrystalline and single crystal zinc both with and without copper on the surface.

Creep rate designated as  $\dot{\epsilon}$ . The constants  $a$  and  $b$  were selected to shift the curves parallel to their original positions for ease of comparison. All the experiments were in the temperature range of 200° to 325°C.

show conclusively that the presence of a thin layer of copper has no effect on the creep behavior of polycrystalline zinc. While particular experiments might indicate an effect of small magnitude, the effect is so small as to be within the scatter of results obtained over many experiments.

The secondary creep rates for zinc in four different conditions were determined in the temperature range 200° to 375°C. The four conditions comprised single crystal and polycrystalline zinc, both with and without the presence of copper in the surface layer. The test procedure consisted of determining for each specimen the creep rates at three different temperatures. After the creep rates were determined for each of the three temperatures, the test at the first temperature was repeated as a check that no appreciable change in the state of the specimen had occurred. The data were plotted with the logarithm of the creep rate as ordinate and the reciprocal of the absolute temperature as abscissa. It is characteristic of the second stage of creep that the creep rate changes very little for relatively large strains. The approximately steady secondary creep rate is known to vary with temperature in close accord with the expression:

$$\text{Creep rate} = A e^{-Q/RT}$$

where  $A$  is a constant;  $e$ , the natural logarithm base;  $Q$ , a quantity known as the activation energy;  $R$ , the gas constant; and  $T$ , the absolute temperature.

The results of these tests have been summarized in the composite plot shown in Fig. 5. In this series of experiments, the objective was to determine the effect of the copper plate on the temperature dependence of creep. Both single and polycrystalline specimens were tested. The lines drawn through the points represent a graphical averaging of the data obtained from numerous tests. The lines have been separated for clarity by shifting the ordinates to a different position on the graph for each type of

specimen. However, the range of temperatures and creep rates were approximately the same for all tests (see Figs. 3 and 4 for typical creep rates), so that a direct comparison of temperature dependence could be made. Individual tests are distinguished by the use of different symbols. The values of  $Q$  were determined from the slopes of these four lines. It will be noted that the same value of  $Q$  was obtained for single crystals without copper, and for polycrystalline zinc with and without copper in the surface layer. Of the four conditions studied only the copper-plated single crystals showed an appreciably different temperature dependence.

An observation was made in regard to the copper-plated single crystals that is of considerable interest. It was found that if, after the creep rate had been determined at three successively higher temperatures, the temperature was lowered for a period of 15 hr, or so, to a point where creep progressed very slowly, reheating the specimen to the original three test temperatures gave appreciably lower creep rates. The log (creep-rate) vs.  $1/T$  plot was a straight line parallel to the line obtained originally, but displaced in the direction of lower creep rates. This effect was observed consistently and is illustrated for a particular test in Fig. 6. The magnitude of the effect may be appreciated by comparing points (1) and (4) which show corresponding creep rates obtained at 275°C before and after the low temperature treatment. This strengthening effect may be due to the clustering of solute atoms around dislocations which reduces their mobility.

### Discussion of Results

Since a relatively thin deposit of copper had such a pronounced effect on the creep behavior of zinc single crystals, it becomes important to consider in what manner the copper exerts its influence. Before discussing the various mechanisms that might account for these results, it is necessary to take into account an additional experimental observation. In all the tests that were performed, diffusion between zinc and copper occurred. The diffusion was quite

Fig. 6—Temperature dependence of copper-plated zinc single crystal showing effect of a period of very slow creep.

After determining points 1, 2, and 3, specimen was cooled under load to 250°C and held at this temperature for 15 hr. Then points 4, 5, and 6 were determined.

rapid; before the specimens attained the test temperature, little visible evidence of the copper deposit remained. However, that the copper remained in the extreme surface layer of the specimen was indicated by the fact that the slight amount of material removed by the anodic treatment in sodium cyanide solution caused the creep rate to increase to the value obtained before plating with copper. It has already been mentioned that during the anodic treatment of the zinc specimens a discontinuous relationship was observed between the applied voltage and the current. When copper was present these discontinuities did not occur. As soon as a surface of essentially pure zinc was exposed, the discontinuities reappeared. This served as a convenient control of the cleaning procedure. Any attempt, therefore, to rationalize the results must take into account the fact that the surface layer consists of a Cu-Zn alloy.

The question arises as to whether the effect of the copper on the creep of zinc single crystals is simply a mechanical one; that is to say, the Cu-Zn surface layer produces a strengthening effect analogous to increasing the specimen diameter by an equivalent thickness of zinc. Stress analyses indicate that this is unlikely and furthermore, if this were the case, no difference in the temperature dependence would be expected between the plated and unplated crystals. The fact that a difference was found suggests that there is a fundamental difference in the creep process for the two surface conditions.

The possibility of developing stresses in the surface layer as a consequence of the application of the copper must also be considered. Such stresses could arise from at least two sources. The existence of stresses in electrodeposited metal is common knowledge. Such stresses may be either tensile or compressive in nature, depending on the metal being deposited and the conditions of electrodeposition. Another source of surface stress lies in the fact that diffusion occurs between the copper and zinc. This causes a change in the lattice parameter at the surface and thus produces a potential localized stress field. While such stresses might conceivably affect the creep rate at a given temperature, it is difficult to see how they could account for a change in the temperature dependence, particularly since the temperature coefficient for unplated zinc was found to be rather insensitive to changes in the stress level. Moreover, the fact that the tests were conducted at elevated temperatures would tend to limit the magnitude of the localized stresses.

Another pertinent question is why the copper deposit had no effect on the creep behavior of polycrystalline zinc. If it is assumed that the generation of dislocations, rather than their migration through the lattice, is rate determining, a possible explanation for this difference in behavior can be offered. It is a reasonable assumption that dislocations can be more easily generated at a surface than in a volume of perfect crystal. In a single crystal the only surface is the external one (neglecting domain boundaries); whereas in a polycrystalline specimen there is a network of internal surfaces as well. Since, in the latter case the external surface is only a small percentage of the total available surface area, a polycrystalline specimen would not be expected to be sensitive to alterations in the external surface. However, evidence has been obtained that indicates such a conclusion may be incorrect. Some tests were performed on polycrystalline "A" nickel, the results of which have been published.<sup>14</sup> A com-

parison was made of the creep behavior of "A" nickel in different environments and surface conditions. It was found that resistance to high temperature creep was much greater in air than in either purified hydrogen or nitrogen. The experiments with "A" nickel were therefore interesting with respect to the strengthening effects that have been reported for single crystals due to an oxide film. Similar results recently have been obtained for copper. It now appears that oxide films are also significant for polycrystalline metals.

In the case of the zinc single crystals the possibility of a volume, rather than a surface effect, would appear to be ruled out by the observation that the removal of a small amount of surface material from a copper-plated specimen caused the creep rate to increase to the value obtained for unplated specimens.

The results presented herein do not constitute a proof that dislocations originate at the surface of single metal crystals during a creep test. It may well be that dislocations are generated internally as postulated by Frank and Reed<sup>15</sup> and that their egress is blocked by the surface layer. At the present time it is not possible to locate the origin of the dislocations. However, additional experiments are now under way which may prove sufficiently critical to establish whether dislocations are generated within the volume of a crystal or at external or grain surfaces.

# Equilibrium Relations in Magnesium-Aluminum-Manganese Alloys

by Benny J. Nelson

AS a part of the fundamental research program of Aluminum Research Laboratories, some data were obtained on the ternary system Mg-Al-Mn. As very little information on the magnesium corner of this diagram has heretofore been published, it seems desirable to make available the values found for the liquidus and solidus surfaces of this system.

## Procedure

The settling procedure was used for the determination of the liquidus compositions. Metallographic examination of quenched samples, and stress-rupture upon incipient melting, were used for the solidus determinations.

The settling procedure has been described in a previous paper.<sup>1</sup> Briefly, this method involved saturating the alloy with manganese at a temperature substantially above that at which the solubility was to be determined, then cooling the melt to the latter temperature, and holding it at that temperature for a substantial period of time. Samples for analysis were carefully ladled from the upper portion of the melt at hourly intervals during the holding period. After the ladling of each sample, the melt was stirred to redistribute some of the manganese that had already settled, because it appeared that when the latter particles of manganese again settled, they aided in carrying down more of the manganese and thus hastened the attainment of equilibrium.

The melts were prepared and held in a No. 8 Tercod crucible holding approximately 4 lb of metal. The manganese was added either in the form of a prealloyed ingot (Dow M) containing about 1.5 pct Mn or by the use of a flux (Dow 250) containing manganese chloride. In calculating the flux additions, it was assumed that the manganese introduced would be equal to 22 pct of the total weight of the flux. Temperatures were measured with an iron-constantan thermocouple enclosed in a seamless steel tube, the lower end of which was welded shut. This protection tube also served as a stirring rod. The samples ladled from the upper portions of the melts at the various intervals were analyzed for aluminum, manganese, and iron.

When making the alloys which were to be used for the determination of the solidus, 2½ in. diam tilt mold ingots were cast, scalped to 2.0 in. in diam, and extruded into ½ in. diam wire. The principal impurities in the melts for this investigation were iron and silicon; their total not exceeding 0.03 pct.

Portions of the wire, approximately 2 in. in length, were enclosed in stainless steel capsules for protection from the atmosphere. Bundles of these capsules, with a dummy capsule containing an iron-constantan thermocouple, were heated inside a large steel block (acting as a heat reservoir) in a closed circulating-air type electric furnace. At ap-

propriate times, the capsules were removed and quenched in water. The wires were examined metallographically to determine the temperature of initial melting.

Short times at temperature were used at the beginning for wire specimens of all alloys to obtain quickly the approximate temperatures at which melting could be first observed. When approximate solidus temperatures had thus been determined, equilibrium heating was attempted. This equilibrium heating consisted of an 8 or 16 hr period at a temperature, about 50°F below the lowest temperature at which melting occurred when short heating cycles were used, followed by further heating for 1 hr periods at consecutive 10° higher temperatures.

The theory for the method of stress-rupture at incipient melting has been well covered<sup>2</sup> and its limitations are recognized. Thus, if the interfacial tensions are such that the first minute quantity of liquid is "bunched up" at the grain boundary junctions instead of spreading out along the grain boundaries,<sup>3</sup> temperatures higher than the solidus are required before melting will be manifested by rupture of the specimen. This point will be elaborated later.

Specimens of the wires with a reduced section (approximately 1/16 in. diam) were suspended vertically in a tubular furnace. The setup used is shown in Fig. 1. The clamp holding the specimen was made from alumel thermocouple wire and the thermocouple was thus completed across the specimen by attaching a chromel wire to its lower end. Temperatures were read from a Speedomax recorder used in conjunction with a calibrated thermocouple. The small weight attached to the specimen and a vibrator attached to the furnace tube, to aid in distributing the molten constituent along the grain boundaries, were used to bring about rupture at a temperature closely approximating the solidus. The specimens were heated at a rate of about 5°C per min. The rupture of the specimens was indicated both by sound and by the action of the recorder. An argon atmosphere containing a small amount of SO<sub>2</sub> was used for protection of the specimen. The assembly was taken out of the furnace immediately following rupture and the specimen removed. Some of the broken specimens were examined metallographically and will be referred to later.

## Results and Discussion

Fig. 2 shows a set of typical time-composition curves for liquid samples of the Mg-Al-Mn alloys used for the settling tests. The data as presented

B. J. NELSON, Junior Member AIME, is Research Metallurgist, Physical Metallurgy Division, Aluminum Research Laboratories, Aluminum Company of America, New Kensington, Pa.

Discussion on this paper, TP 3133E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 11, 1951. Detroit Meeting, October 1951.

Fig. 1 (left)—Apparatus for determining solidus temperatures in magnesium alloys by the stress-rupture method.

Fig. 2 (right)—Liquid solubility of manganese in Mg-4.5 pct Al alloy as determined by settling tests.

Fig. 3 (lower left)—Liquid solubility of manganese in Mg-Al alloys as determined by limiting values on settling test curves.

Fig. 4 (lower right)—Liquid solubility of manganese in Mg-Al-Mn alloys plotted as the logarithm of atomic percentage of manganese vs. the reciprocal of absolute temperature.

ture for both aluminum and manganese for the different nominal aluminum content series.

Fig. 3 shows the liquidus curves in weight percentage of manganese for these alloys vs. degrees F, while Fig. 4 shows the solubility of manganese in atomic percentage vs. the reciprocal of the absolute temperature (corresponding degrees F being indicated). The values for zero pct Al are taken from the results of Tiner.<sup>4</sup> The liquidus curves take a decided change in slope in the neighborhood of 1450°F, possibly indicating a peritectic reaction.

As would be expected, the addition of aluminum to the Mg-Mn alloys lowers the solubility of man-

show that, in general, supersaturation is established before the settling period begins. The manganese concentration usually rises during the period in which the melt is held at 1600°F and after the temperature is lowered, falls rather quickly to a limiting value, which is taken as the solubility of manganese in the alloy at the lower temperature. In all cases, solubility curves were determined on the basis of the average manganese contents during the last few hours of settling. It should further be brought out that the aluminum content as given for the curves is the nominal composition; the actual content for each sample varied somewhat from this nominal. Table I gives the "limiting" values at each tempera-

Fig. 5—Solidus temperatures in magnesium base Mg-Al-Mn alloys and the Mg-Al solidus line.

Fig. 6—Microstructure of Mg-7.25 Al-2.11 Mn alloy fractured at 1013°F. Notice narrowness of grain boundaries and the absence of bunching up at the grain junctions. Etched with Keller's etch. X500.

\* Not determined.

\*\* Equilibrium conditions not attained.

ganese in the ternary alloy. The striking influence of small amounts of aluminum in decreasing the liquid solubility of manganese in these alloys is readily apparent.

It should be emphasized that the numerical value of atomic percentage of manganese for each point on all of these curves was calculated separately. This was necessary because in all cases there was some change in the aluminum content as the limiting solubility of manganese was reached; the best average for the limiting values of both aluminum and manganese was used as is shown in Table I.

#### Solidus Temperatures in Mg-Al-Mn Alloys

As stated earlier, both metallographic examination and the stress-rupture method were used to determine the solidus temperatures of the Mg-Al-Mn alloy wires.

Table II gives the solidus temperatures of the wires as determined by these two methods. Considering the limitations of each method, the agreement between the results is fairly good, particularly for the alloys of low to medium aluminum content.

Fig. 5 shows the effect of manganese on the solidus temperature as determined by the stress-rupture method; the aluminum values listed for the curves are averages. It is seen that the manganese significantly raises the solidus temperature of Mg-Al alloys. This figure also shows the Mg-Al solidus line when these curves are extrapolated to zero pct Mn, together with the Mg-Al solidus data of Hume-Rothery and Raynor.<sup>5</sup> The agreement between the present data and that of ref. 5 for the solidus is fair.

It was mentioned earlier that the distribution of the liquid phase would have an influence upon the temperature of fracture. The microstructure of one of the specimens from the stress-rupture test is shown in Fig. 6. No tendency for the melted constituent to "bunch up" at the grain boundaries is noted; the film of liquid along the grain boundaries is so thin it is difficult to show in the micrograph.

#### Conclusions

Liquidus and solidus determinations have been made in the ternary system Mg-Al-Mn and these are shown by a series of curves. The following conclusions can be drawn:

1—The solubility of manganese in liquid magnesium is greatly depressed by the addition of a small amount of aluminum, and is further depressed by increasing amounts of aluminum in the alloys.

2—There is a discontinuity in the slope of the liquidus surface in the magnesium corner at about 1450°F.

3—The solidus temperature of alloys in the magnesium corner decreases markedly with increasing aluminum content for alloys having approximately equal manganese contents.

4—The solidus temperature increases substantially with increasing manganese.

#### Acknowledgment

The author wishes to express his appreciation of the assistance given by his associates in Aluminum Research Laboratories, and especially to L. A. Willey who designed and built the apparatus for the stress-rupture determinations.

# Crystal Structure of $\text{UAl}_4$

by Bernard S. Borie, Jr.

THE U-Al binary system has been studied by Kaufmann and Gordon.<sup>1</sup> They have shown that three intermetallic compounds occur in the system:  $\text{UAl}_3$ ,  $\text{UAl}_2$ , and a third compound tentatively identified as  $\text{UAl}_4$ .  $\text{UAl}_3$  is simple cubic,  $a_0 = 4.26\text{\AA}$ . Its unit cell contains one formula weight, and it is isomorphous with  $\text{AuCu}_3$ .  $\text{UAl}_2$  is face-centered cubic,  $a_0 = 7.72\text{\AA}$ , with eight formula weights per unit cell. Rundle and Wilson have shown that it is isomorphous with  $\text{Cu}_2\text{Mg}$ .<sup>2</sup> A Debye-Scherrer pattern of the Al-rich compound indicated a more complex structure than either  $\text{UAl}_2$  or  $\text{UAl}_3$ . The following is a report of an investigation of the crystal structure of this compound and a determination of its stoichiometric formula.

A melt of uranium (99.9 pct pure) and aluminum (99.9 pct pure) was prepared which contained about 25 pct U by weight. It was cooled from  $950^\circ$  to  $650^\circ\text{C}$  at a rate of  $500^\circ$  per hr and then taken from the furnace and air cooled. An X-ray diffraction pattern of the ingot showed only lines of aluminum and the Al-rich compound. Filings from the ingot were reacted with a solution of sodium hydroxide, producing a fine black powder, the diffraction pattern of which showed no traces of aluminum. A comparison of the Debye-Scherrer pattern of our sample with the data published by Kaufmann and Gordon<sup>1</sup> showed that it is identical with the Al-rich phase which they reported.

Single crystals were obtained by cooling the melt more slowly (about  $50^\circ\text{C}$  per hr). After reaction with sodium hydroxide, the crystals appeared as small black needles attached to the ingot surface.

## Cell Size, Space Group, and Uranium Positions

A series of Weissenberg photographs for rotation about two of the crystallographic axes, taken with copper radiation filtered through nickel foil, revealed an orthorhombic cell of dimensions:

$$\begin{aligned} a &= 4.41 \pm 0.02\text{\AA} \\ b &= 6.27 \pm 0.02\text{\AA} \\ c &= 13.71 \pm 0.03\text{\AA} \end{aligned}$$

Reflections of the type  $hkl$  were observed only if:

$$h + k + l = 2n,$$

of the type  $hk0$  only if:

$$h = 2n \text{ and } k = 2n,$$

of the type  $h0l$  only if:

$$h + l = 2n,$$

and of the type  $0kl$  only if:

$$k + l = 2n.$$

Hence, the cell is body-centered with an  $00l$  glide plane. The evidence for the existence of the glide plane is the observed extinction of 23 possible re-

Fig. 1—Comparison of observed and calculated X-ray patterns for  $\text{UAl}_4$ .

flections of the type  $hk0$  with at least one index odd.

There are only two space groups consistent with these data:  $C_{2v}^{22} - I2ma$  and  $D_{2h}^{28} - Imma$ .<sup>3</sup> The possible sets of atomic positions for these space groups are:

$I2ma$ :

$$(0\ 0\ 0; \frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}) +$$

$$4: (a) x\ 0\ \frac{1}{2}; x\ \frac{1}{2}\ \frac{1}{2}$$

$$(b) x\ \frac{1}{4}\ z; x\ \frac{3}{4}\ \bar{z}$$

$$8: (c) x\ y\ z; x\ \bar{y}\ \bar{z}; x, \frac{1}{2} + y, \bar{z}; x, \frac{1}{2} - y, z$$

$Imma$ :

$$(0\ 0\ 0; \frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}) +$$

$$4: (a) 0\ 0\ 0; 0\ \frac{1}{2}\ 0$$

$$(b) 0\ 0\ \frac{1}{2}; 0\ \frac{1}{2}\ \frac{1}{2}$$

$$(c) \frac{1}{4}\ \frac{1}{4}\ \frac{1}{4}; \frac{3}{4}\ \frac{1}{4}\ \frac{1}{4}$$

$$(d) \frac{1}{4}\ \frac{1}{4}\ \frac{3}{4}; \frac{3}{4}\ \frac{1}{4}\ \frac{3}{4}$$

$$(e) 0\ \frac{1}{4}\ z; 0\ \frac{3}{4}\ \bar{z}$$

$$8: (f) x\ 0\ 0; \bar{x}\ 0\ 0; x\ \frac{1}{2}\ 0; \bar{x}\ \frac{1}{2}\ 0$$

$$(g) \frac{1}{4}\ y\ \frac{1}{4}; \frac{3}{4}\ \bar{y}\ \frac{3}{4}; \frac{3}{4}\ y\ \frac{1}{4}; \frac{1}{4}\ \bar{y}\ \frac{3}{4}$$

$$(h) 0\ y\ z; 0\ \bar{y}\ \bar{z}; 0, \frac{1}{2} + y, \bar{z}; 0, \frac{1}{2} - y, z$$

$$(i) x\ \frac{1}{4}\ z; \bar{x}\ \frac{3}{4}\ \bar{z}; \bar{x}\ \frac{1}{4}\ z; x\ \frac{3}{4}\ \bar{z}$$

$$16: (j) x\ y\ z; x\ \bar{y}\ \bar{z}; x\ \bar{y}\ \bar{z}; x\ y\ z; x, \frac{1}{2} + y, \bar{z}; x, \frac{1}{2} - y, z; x, \frac{1}{2} - y, z; x, \frac{1}{2} + y, \bar{z}$$

Though density measurements on different samples were found to vary somewhat, they were all within the range  $5.7 \pm 0.3$  g per cu cm. If it is assumed that the unit cell contains four formula weights of  $\text{UAl}_4$ , it is 6.5 g per cu cm. If there were as many as eight uranium atoms per unit cell, the

B. S. BORIE, JR., is with the Metallurgy Division, Oak Ridge National Laboratory, Oak Ridge, Tenn.

Discussion on this paper, TP 3126E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 20, 1951. Detroit Meeting, October 1951.

density would be in excess of 8.5 g per cu cm. Therefore the cell contains four uranium atoms.

If the uranium atoms occupied four-fold positions (a), (b), (c) or (d) of *Imma* or (a) of *I2ma*, for reflections of the type 00*l* the uranums would all be in phase and the reflections should all be fairly uniformly strong. However, the reflections of this type not suppressed by the space group were observed to vary from very strong to very weak. Hence the uranium atoms must occupy either positions (e) of *Imma* or (b) of *I2ma*. By a proper choice of the origin for positions (b) of *I2ma*, so the uranums all lie in planes  $x/a = 0$  and  $x/a = \frac{1}{2}$ , these positions may be made equivalent. It was found that a parameter of  $z/c = 0.111$  fits the observed intensities quite well.

### Determination of the Stoichiometric Formula

Since the space group requires that the number of aluminum atoms per unit cell be a multiple of four, and since there are four uranium atoms per unit cell, the ideal cell must contain four formula weights and the formula must be of the type  $UAl_x$ .

Chemical analyses, as did the density measurements, suggest that the structure occurs over a range of composition. Various samples, which by spectrographic methods were found to contain only traces of impurities and the X-ray patterns of which showed no lines other than those of the compound, were found to have uranium compositions ranging from 64.2 to 66.3 pct by weight. This corresponds to a range in the formula of from  $UAl_{4.0}$  to  $UAl_{4.5}$ . Hence these data yield little information other than that the ideal formula must be either  $UAl_4$  or  $UAl_5$ .

However, it may be shown, on the basis of the atomic radii of uranium and aluminum and the symmetry of the possible space groups, that the formula must be  $UAl_4$ . On the basis of the atomic diameters of the two elements, the U-Al interatomic distance should not be less than 2.73 Å, and the Al-Al distance should be about 2.7 Å.

Positions (a), (c), (d), (f), (g), (i), and (j) of space group *Imma* would all require either a U-Al distance or an Al-Al distance to be less than 2.3 Å. Hence the aluminums must not occupy these positions. It is found, when the remaining three sets of positions are considered, that to satisfy the atomic radii, not more than 16 aluminum atoms may occupy the unit cell; they must be in a set of four in positions (b), a set of four in (e), and a set of eight in (h).

For space group *I2ma*, to satisfy the atomic radii, the 16 aluminums must be in a set of four in (a), a set of four in (b), and a set of eight in general positions (c).

### Determination of the Aluminum Positions

Except for the  $x$  parameters, positions (b), (e), and (h) of *Imma* are equivalent to (a), (b), and (c) of *I2ma*. It was found that to satisfy the interatomic distances, the aluminum atoms must lie in planes  $x/a = 0$  and  $x/a = \frac{1}{2}$ , as described by *Imma*, or very nearly so. It was assumed that this is the case.

A set of approximate aluminum positions for space group *Imma*, chosen to be consistent with the observed X-ray intensities and the atomic radii, are:

- 4 Al in (b)
- 4 Al in (e),  $z/c = -0.111$
- 8 Al in (h),  $y/b = -0.033$ ,  $z/c = 0.314$

A comparison of the observed and calculated X-ray patterns for these positions is shown in Fig. 1. The observed pattern was obtained using a North

Fig. 2—Comparison of observed and calculated neutron patterns for  $UAl_4$ .

American Phillips spectrometer. The pattern was calculated using the formula:

$$I \propto \frac{(1 + \cos^2\theta) pF^2}{\sin^2\theta \cos \theta}$$

The line widths were chosen to correspond to those observed. An effort to refine these parameters by a Fourier synthesis of the electron density projected on the  $xy$  plane failed. In spite of the fact that the crystal used was quite small, its absorption coefficient was large enough and its shape sufficiently irregular to make accurate determination of the structure factors impossible.

Since the scattering factor of uranium is about seven times that of aluminum, the general characteristics of the calculated diffraction pattern are not very sensitive to variations in the aluminum positions. However, for neutrons the scattering factor of uranium is only slightly more than twice that of aluminum. Hence, the neutron diffraction pattern should provide valuable evidence for the light atom positions. A neutron pattern was obtained and is shown in Fig. 2, compared with the calculated pattern for the aluminum positions listed above. The intensity was taken to be proportional to:

$$\frac{1}{\sin \theta \cos \theta} pF^2$$

Table I. Interatomic Distances of  $UAl_4$

| Atom    | No. of Neighbors | Kind of Neighbors | Distance, Å |
|---------|------------------|-------------------|-------------|
| U (4e)  | 3                | Al (4e)           | 3.14        |

The line widths were again chosen to correspond to the observed pattern.

### Summary and Discussion

The Al-rich, U-Al intermetallic compound has the formula  $UAl_4$ . Its unit cell is body-centered orthorhombic,  $a = 4.41\text{\AA}$ ,  $b = 6.27\text{\AA}$ , and  $c = 13.71\text{\AA}$ . The cell contains four formula weights and the space group is either  $I2ma$  or  $Imma$ . The atoms occupy the following positions of  $Imma$ :

|         |                                                                                                                       |
|---------|-----------------------------------------------------------------------------------------------------------------------|
|         | $(0\ 0\ 0; \frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}) +$                                                                  |
| 4 U in  | (e) $0\ \frac{1}{4}\ z; 0\ \frac{3}{4}\ \bar{z}; z/c = 0.111$                                                         |
| 4 Al in | (e) $0\ \frac{1}{4}\ z; 0\ \frac{3}{4}\ \bar{z}; z/c = -0.111$                                                        |
| 4 Al in | (b) $0\ 0\ \frac{1}{2}; 0\ \frac{1}{2}\ \frac{1}{2}$                                                                  |
| 8 Al in | (h) $0\ y\ z; 0\ \bar{y}\ \bar{z}; 0, \frac{1}{2} + y, \bar{z}; 0, \frac{1}{2} - y, z$<br>$y/b = -0.033\ z/c = 0.314$ |

The number and kinds of nearest neighbors and the interatomic distances for the various atoms in the unit cell are given in Table I. With the exception of the Al-Al distance of  $2.57\text{\AA}$ , the interatomic distances are consistent with the separations pre-

dicted by the sum of the atomic radii. Though the distances reported are not highly accurate—since the light atom positions are only approximate—it is possible that this separation may be somewhat less than the atomic diameter of aluminum given by Goldschmidt. Axon and Hume-Rothery have found that the apparent atomic radius of aluminum in its face-centered cubic structure is large.<sup>4</sup> They predict that the corrected atomic diameter of aluminum is probably less than  $2.71\text{\AA}$ .

The distribution of the atoms in the unit cell as viewed along the  $a$  axis is shown in Fig. 3. The ones shown in heavy outline are uranium. The atoms are arranged in two layers parallel to the  $yz$  plane at  $x/a = 0$  and  $x/a = \frac{1}{2}$ . The coordination numbers are: for uranium, 13; for the aluminum atoms in (b), 12; in (e), 13; and those in (h), 11.

The chemical analyses and density measurements, which are somewhat inconsistent with the ideal structure, may be explained by assuming either that some uranium sites are unoccupied or that some are occupied by aluminum atoms.

There are numerous structures in which such lattice defects exist.  $CuSn$ , which has the nickel arsenide structure, is invariably found to have a deficiency of tin of about 4.6 atomic pct. A similar situation exists in the phase  $CuAl$ . Lead dioxide is known to retain its structure down to the composition  $PbO_{1.66}$ . Other compounds having defect structures are  $NaWO_3$ ,  $\gamma-Al_2O_3$ , and  $FeS$ , all of which have cation deficiencies.  $NaWO_3$  apparently retains its structure with less than one third of the sodium sites occupied.

An interesting similarity between this structure and the simple cubic structure of  $UAl_3$  exists. This is illustrated in Fig. 4 which compares unit cells of the two structures. The eight-fold aluminum atoms in  $UAl_3$  have been omitted.

It is clear from Fig. 4 that the  $UAl_4$  unit cell, except for the eight-fold aluminum atoms, could be constructed from plates of  $UAl_3$ . The plates would have for their faces 110 planes of the cubic structure and would be of a thickness equal to the spacing of the 110 planes of  $UAl_3$ . The normal to the planes would be parallel to the  $c$  axis of  $UAl_4$ .

Actually the  $UAl_3$  cell would have to be slightly expanded for this construction to be possible. The U-U separation in  $UAl_4$  is about 3.5 pct greater than it is in  $UAl_3$ . However, the cubic symmetry is almost perfectly maintained. For this to be so, the U-U separation in the  $bc$  plane,  $a$ , and  $b/\sqrt{2}$  would have to be equal. These three distances are respectively,  $4.37\text{\AA}$ ,  $4.41\text{\AA}$ , and  $4.43\text{\AA}$ .

Hence the structure may be thought of as  $UAl_3$  plates held together by extra aluminum atoms.

# Solidification of Lead-Tin Alloy Droplets

by J. H. Hollomon and D. Turnbull

THERE is a large body of evidence<sup>1-3</sup> indicating that solidification during the liquid-solid transition is usually induced by heterogeneities present in the liquid. By dispersing liquid metals into small droplets, the impurities responsible for catalyzing solidification are isolated within a small number of these droplets. The effect of the foreign body therefore is restricted to a single drop by this technique. Thus upon cooling below the melting temperature, solidification is initiated by homogeneous nucleation in the majority of the droplets that do not contain impurities.

In the case of solidification of liquid metals, the activation energy for nucleation is so great that its rate changes by orders of magnitude for a change in temperature of only several degrees centigrade.<sup>4</sup> Effectively homogeneous nucleation occurs at a critical temperature upon continuous cooling. Thus by microscopic observation of single particles during cooling, a temperature at which the rate of homogeneous nucleation becomes sensible can be determined.<sup>5</sup> Since at the temperatures at which nucleation occurs in the absence of impurities the rate of crystal growth is extremely rapid, the temperature at which the entire particle solidifies is very nearly the temperature at which the nucleation of the solidification occurs. Thus for liquids that freeze at high temperatures the onset of nucleation can be established by simply observing the temperature at which the marked heat evolution and increase in brightness of the particle occur. For liquids that freeze at lower temperatures the onset of nucleation can be determined by a rumpling and change in shape of the particle resulting from its solidification. The microscopic technique for observing the solidification of small particles has already been described.<sup>5</sup>

In earlier papers the nucleation of solidification of pure metals<sup>6, 7</sup> and of alloy systems<sup>7</sup> showing complete liquid and solid solubility have been described. In the present paper, the observations are extended to a simple eutectic system (Pb-Sn) where the possibility of the formation of two solid phases exists.

Metals for the investigation were obtained from the American Smelting and Refining Co. in the form of pure lead and pure tin, 99.8 and 99.9 pct purity, respectively. An ingot of each of the pure metals was made into shot by heating the metals at a temperature about 50°C in excess of the melting point and pouring the liquid slowly into a container of water at 15°C. Samples of the shotted pure metals were weighed out to make alloys containing 5, 10, 15, 20, 25, 30, 40, 50, 60, 70, 80, and 90 atomic pct Pb. Samples of each alloy were then melted in separate beakers. Each melt was poured through a pyrex

J. H. HOLLOWOM, Junior Member, and D. TURNBULL, Associate Member AIME, are associated with the Research Laboratory, General Electric Co., Schenectady.

Discussion on this paper, TP 3104E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, Jan. 30, 1951. Detroit Meeting, October 1951.

Table I. Analyses of Poured Metal

funnel into a cylindrical mold ( $\frac{5}{8}$  in. ID). The casting solidified in 10 to 20 sec. The inside of the mold as well as the funnel through which the metal was poured were coated with graphite to eliminate adherence of the metal. Analyses were performed on some of the compositions and are given in Table I.

The compositions also were checked for these samples and for those that were not analyzed by determining the spread between the liquidus and the solidus upon melting the small metal particles. These measurements agreed as well with the nominal compositions as the analyses listed above.

## Results

The results of the supercooling experiments for the several alloys are summarized in Table II and plotted on the constitution diagram in Fig. 1. Data for the pure lead and pure tin were taken from earlier investigations.

The values for the maximum supercooling of the several alloys are the average of several determinations on a number of drops of each alloy. The maximum value in any determination was within about 2 pct of the average. For the alloys containing from 20 to 60 atomic pct Sn, inclusive, two marked changes of the surface structure were observed upon cooling. At the higher temperature, after the first appearance of the solid phase it continued to grow slowly at a constant temperature and then stopped. At the lower temperature the alteration of surface structure was abrupt. For the alloys containing from 70 to 95 atomic pct Sn, inclusive, an abrupt change in surface structure was observed at a single critical temperature.

Fig. 1—Equilibrium diagram of Pb-Sn system with solidification temperature of small alloy droplets indicated.

The alloy containing 20 atomic pct Sn completed its solidification at a temperature of about 170°C. However, in all these experiments summarized in Table II and Fig. 1 the cooling time from the maximum temperature (where the drop was liquid) to the temperature of complete solidification was of the order of 10 min. It was believed that the second critical temperature for complete solidification of the 20 and 30 atomic pct alloys resulted from segregation due to lack of equilibration of the composition. Thus a second set of experiments were performed with the 20 pct alloy in which the specimen was held at a temperature of about 220°C for several hours. This treatment resulted in less segregation as determined metallographically than did the more rapid cooling, and the lower critical temperature was not observed. However, it is believed that the two critical temperatures for the 40, 50, and 60 pct alloys would be observed if the equilibration with respect to composition was complete.

A droplet from each of the several compositions was cross-sectioned and examined metallographically after solidification. Typical micrographs are presented in Figs. 2, 3, 4, and 5. Fig. 2 is the micro-

structure of the alloy containing 70 pct Pb. The alloy of Fig. 3 contains 25 pct Pb and that of Figs. 4 and 5, 15 pct Pb. All the micrographs are at 500 magnification excepting that Fig. 5 was taken at 100X. In Fig. 2 the light constituent is the tin phase trapped by the dendritic arms of the lead. Conversely, in Figs. 4 and 5, small particles of lead have been trapped by the dendritic arms of tin.

### Discussion

In the phase diagram in Fig. 6, the liquidus lines have been extrapolated into the metastable region. In an alloy of 50 atomic pct Sn, lead nucleates homogeneously at the temperature marked *x*; the alloy being significantly supercooled (approximately 40°C). As the small droplet is further cooled the composition of the liquid tends to follow the  $\alpha$ -liquidus line and its extension into the region of metastability. At the temperature marked with the triangle that liquid becomes sufficiently supercooled with respect to the  $\beta$ -liquidus that tin nucleates. Thereafter both lead and tin crystals grow. The actual composition of the liquid phase when tin nucleates must fall on the extended  $\alpha$ -liquidus and is marked with a circle at the same temperature as that of the triangle. For the alloy containing 10 atomic pct Sn the droplet solidified completely as soon as nucleation of lead took place.

For the 20 and 30 atomic pct Sn alloys the solidification began with the formation of a lead-rich phase at the temperatures marked *x* and was completed gradually if the temperature was lowered slowly. Consider now an alloy containing 70 atomic pct Sn. Upon supercooling approximately 45°C, the alloy completely solidifies. After the formation of the lead-rich nucleus the composition of the residual liquid is given by the  $\alpha$ -liquidus composition at that temperature. At this composition and temperature the solution is already supercooled below the temperature of rapid nucleation of the tin-rich phase in the presence of lead indicated by the circle. Thus a line joining the points marked with *x* in Fig. 6 represents the temperature at which the lead-rich phase

Fig. 2 (upper left)—Microstructure of alloy droplet after solidification, 30 atomic pct Sn. X500.

Fig. 3 (upper right)—Microstructure of alloy droplet after solidification, 75 atomic pct Sn. X500.

Fig. 4 (lower left)—Microstructure of alloy droplet after solidification, 85 atomic pct Sn. X500.

Fig. 5 (lower right)—Microstructure of alloy droplet after solidification, 85 atomic pct Sn. X100.

first nucleates from the liquid solution. The triangles represent the temperature at which the tin-rich phase subsequently nucleates from the supercooled liquid solution. Since the nucleation of the tin-rich phase occurs at a temperature and composition on the extended liquidus line the temperature at which the tin-rich phase first forms is independent of the compositions of the alloy for percentages less than the 70 atomic pct Sn.

Consider now an alloy containing 90 atomic pct Sn. It is noted that complete solidification is accomplished by cooling this alloy to a single temperature even though it is not supercooled below the extended  $\alpha$ -liquidus line. The interpretation of this result is that tin nucleates first with a supercooling of approximately 75°C following which the composition of the liquid becomes that given by the extended  $\beta$ -liquidus line. At this composition the temperature is below that necessary to nucleate the lead-rich phase. Thus immediately upon the formation of the first tin-rich nucleus and following its growth, the liquid is supersaturated and supercooled sufficiently for the lead-rich phase to nucleate and grow. Particles of the lead-rich phase will nucleate within the liquid trapped in the interstices of the tin-rich phase as illustrated in Figs. 4 and 5. Thus the curve joining the squares gives the temperature at which the tin-rich phase first nucleates. With an alloy containing approximately 80 atomic pct Sn the temperatures at which the tin and lead-rich phase nucleate are very nearly the same.

The fact that the tin-rich phase that forms following the formation of the lead-rich phase solidifies at a temperature of about 10° above the curve of temperature of first solidification of tin-rich alloys indicates that possibly the lead-rich phase has a mild catalytic effect on the nucleation of the tin-rich phase. The effect is less than 10° and amounts to only a little more than the experimental errors. Also there is some additional error due to the extrapolation of the  $\alpha$ -liquidus curve.

In some systems in which two solid phases may form from a single liquid solution one of the phases may catalyze the nucleation of the second phase. Experiments in other systems should be performed to determine the prevalence of such catalytic action.

The degree of supercooling is determined by the differences in free energy between the solid and the liquid and upon the interfacial free energy between that solid and the melt. An interpretation of the slight decrease in the amount of supercooling with a small addition of tin to lead or of lead to tin may be that this addition decreases the interfacial tension between the solid that nucleates and the liquid from which it forms.

In pure metals it is possible to calculate from the theory of homogeneous nucleation and from the maximum supercooling of small droplets the interfacial free energy between the liquid and solid phases. However, in an alloy system, for a liquid of a given composition both the interfacial free energy between this liquid and solid and the free energy difference between this liquid and the solid will be a function of the composition of the solid. Thus even though the free energy as a function of composition is known it is not possible to calculate the interfacial free energy unless the composition of the nucleus is known or the dependence of the interfacial free energy on the composition is known. The functional relationship between the interfacial free energy between liquid and solid and the composition of the

Fig. 6—Solidification temperatures of Pb-Sn alloy droplets in relation to extended equilibrium lines.

solid can in principle be determined experimentally. Theoretical analysis of these experimental results in terms of nucleation theory will not be possible until these measurements have been made.

### Summary

1—The solidification of Pb-Sn alloy droplets (30 to 50 micron diam) was observed as a function of composition by a microscopic technique.

2—On the lead-rich side of the eutectic the initial solidification temperature,  $T_i$ , is about 35° to 45°C below the liquidus,  $T_l$ , excepting that for pure lead  $T_m - T_i = 80^\circ$ .

3—On the tin-rich side of the eutectic  $T_m - T_i \sim 60^\circ$  to 75°C excepting that for pure tin  $T_m - T_i = 110^\circ$ .

4—In the lead-rich alloy a second temperature of abrupt solidification  $T_i \sim 160^\circ$  and independent of composition was observed. It is believed that  $T_i$  is the initial solidification temperature of the tin-rich solution that remains liquid after the formation and growth of the lead-rich crystalline phase.

5—There is some evidence that the lead-rich crystalline phase has a mild catalytic effect on the formation of nuclei for the growth of the tin-rich solid solution.

# Creep Characteristics of Some Platinum Metals at 1382°F

by R. H. Atkinson and D. E. Furman

HITHERTO the practical creep testing of precious metals has received little or no attention. The only previous creep tests of precious metals have been made with wires under conditions such as to yield much more rapid rates of creep than in engineering tests.<sup>1, 2</sup> Up to the present time the value of creep bars of adequate size, in the absence of real need for engineering data, has deterred investigators. However, the increasing use of platinum at high temperatures has demonstrated the need for reliable creep data for the guidance of engineers, especially those engaged in designing certain specialized chemical plant equipment. In order to supply this need, creep tests were conducted at 1382°F (750°C) on 0.290 in. diam specimens of platinum, 90 pct Pt, 10 pct Rh and palladium.

The platinum was high purity, nominally 99.95 pct Pt. The 90 pct Pt, 10 pct Rh was of the same high quality as is used for making gauzes for the catalytic oxidation of ammonia. The palladium was also of high purity; two batches of palladium bars were tested, one deoxidized with calcium boride and the other with aluminum. Spectrographic examination of the palladium confirmed its good quality; the only significant impurities apart from the residual deoxidizers were traces of silicon and lead.

## Procedure

The creep bars, which were furnished by Baker and Co. to our specification, were 6¾ in. in overall length with a 4½ in. (4 in. gage length) reduced section 0.290 in. in diam and had the ends threaded (¾-NC16). It may be of interest that the bars were valued at up to \$600 each. The specimens were supplied in a 50 pct cold-worked condition to facilitate attachment of the creep extensometer, which was of the push rod type. Because of the softness of the platinum and palladium, the extensometer rings were secured to the test section by means of circular knife edges instead of the usual pointed set screws. The extensometer rods extended through the bottom of the furnace and readings were taken with a 0.0001 in. "Last Word" dial gage fastened to the rods for the duration of the test. The bars were directly loaded by hanging weights from the lower specimen grip. All tests were conducted at 1382°F ± 2°F, and an effort was made to maintain the temperature gradient over the test section within 2°F. The ends of the furnace tube were packed with asbestos wool, which allowed a very slow circulation of air through the tube.

Annealing was accomplished in the creep furnace before the load was applied. The platinum and palladium specimens were annealed at the test tem-

Fig. 2—Platinum, 10 pct Rhodium creep curves at 1382°F.

perature for about 17 and 24 hr respectively; in the case of the rhodiplatinum it was found expedient to anneal for 1 hr at 1922°F (1050°C). Pilot samples cut from the same stock as the bars were used to check annealing procedures. Pertinent measurements of grain size and hardness were recorded.

## Results and Discussion

The creep data obtained are given in Table I and the creep curves are plotted in Figs. 1, 2, and 3.

Two platinum specimens, tested under a stress of 250 psi, had almost identical creep rates at 2000 hr, namely 0.000008 and 0.000009 pct per hr. A third platinum specimen, stressed at 400 psi, had a creep rate at 2000 hr of 0.000026 pct per hr; the reason for a rather sharp decrease in creep rate during the period from 1200 to 1600 hr is unknown.

As it was thought that 90 pct Pt, 10 pct Rh would have a lower creep rate than platinum, the first sample was tested at 400 psi; however, the creep rate was approximately 50 pct greater. Microexamination revealed that differences in grain size might be responsible for the unexpected result, as annealing at 1382°F developed an average grain diameter of 0.0021 in. in the rhodiplatinum specimen compared with 0.004 in. in the platinum bar. Annealing the alloy for 1 hr at 1922°F (1050°C) increased the average grain diameter to 0.0032 in. and materially improved the creep resistance, making it much better than platinum. A second specimen annealed at 1922°F (1050°C) and tested under a stress of 550 psi had a creep rate of 0.000022 pct per hr at 2000 hr, which was still substantially lower than that shown by the specimen annealed at 1382°F (750°C) and stressed at only 400 psi.

In contrast to the creep behavior of the platinum and rhodiplatinum specimens, the palladium bars, whether deoxidized with calcium boride or aluminum, were characterized by high first stages of creep. However, after about 1200 hr of test, the creep

rates decreased rather rapidly to much smaller values. As the changes in creep rate occurred after approximately 1200 hr regardless of whether the specimens were stressed at 250 or 150 psi, it was decided to pretreat another specimen at the test temperature for a similar length of time. This pretreatment of the unstressed creep specimen completely eliminated the high first stage of creep and may have improved the secondary creep rate too. Incidentally the specimen did not change in length during pretreatment. It was thought at first that the good effect of the extended anneal might be associated with further stress relief or an increase in grain size, but measurements of hardness and grain size did not support this view. However, something else had been happening which might affect

Fig. 3—Palladium creep curves at 1382°F.  
A—Bar deoxidized with aluminum.  
B—Bar deoxidized with calcium boride.

the creep rate. Microexamination of bars after tests of 3000 hr duration revealed intergranular attack and formation of subscale to a depth of about 0.055 in., Fig. 4, and the rate of penetration indicated that the major part of this internal oxidation probably occurred during the first thousand hours at testing temperature. The improvement effected by the extended anneal might be due to its affording an opportunity for the subsurface reaction to reach equilibrium before the load was applied.

A comparison of the creep strengths of the three materials at 1382°F (750°C) on the basis of the estimated stresses required to give a creep rate of 0.00001 pct per hr at 2000 hr (or 3000 hr in the case of palladium) may be made from the log stress-log creep rate plot of Fig. 5. For platinum and 90 pct Pt, 10 pct Rh stresses of 270 psi and 340 psi, respectively, would give creep rates of 0.00001 pct per hr at 2000 hr. In the case of palladium it is esti-

Fig. 4—Palladium creep bar after 3090 hr test. Longitudinal section shows intergranular attack and formation of subscale extending to a considerable distance below the surface (SS). True depth of attack as observed in a cross-section was 0.052 in. Etch: Electro, AC; 5 pct NaCN. X28.

Fig. 5—Creep data at 1382°F.

mated that a stress of 440 psi would give the same creep rate at 3000 hr. The evaluation of the creep strength of palladium is made at 3000 hr because the creep data at 2000 hr are influenced by the high first stage, which it was shown later could be eliminated by suitable pretreatment.

The surprising finding that palladium is apparently more creep resistant than either platinum or 90 pct Pt, 10 pct Rh at the given temperature calls for comment. The larger grain size of the palladium does not seem to account adequately for its superiority. It would almost seem as if internal oxidation had strengthened the palladium instead of weakening it. The question also arises as to whether very pure palladium free from excess deoxidizer would also be more creep resistant than pure platinum. To answer this question it would be necessary to measure the creep rate of specimens prepared from

### Summary

The creep rates of pure platinum, 90 pct Pt, 10 pct Rh and pure palladium at 1382°F (750°C) have been determined using bars 0.290 in. in diam and stresses of 150 to 550 psi in tests lasting up to 3000 hr. The creep rate curves of platinum were normal for stresses of 250 and 400 psi. The creep rate of 90 pct Pt, 10 pct Rh, provided it was given a brief high temperature anneal (1 hr at 1922°F) for grain enlargement, was below that of pure platinum. The creep rate of normally annealed palladium under stresses of 150 and 250 psi was very high for the

first 1200 hr but fell to a low value thereafter. Heating the palladium at 1382°F (750°C) for 1200 hr virtually eliminated the first stage of creep and also lowered the rate in the second stage.

### Acknowledgment

The authors wish to take this opportunity of thanking Baker & Co., of Newark, N. J., for their cooperation both in lending the platinum metals and in preparing the specimens. The authors are grateful to N. B. Pilling, Director of Research, International Nickel Co., for permission to publish these data, to E. M. Wise for suggestions and to W. T. Coughlin and J. W. Whitney for their assistance.

## Technical Note Deformation Texture of Body-Centered Cubic Metal Wires

by W. R. Hibbard, Jr., A. E. Roswell, and A. E. Schuetz

THE drawn wire texture of body-centered cubic iron,<sup>1</sup> tungsten,<sup>2</sup> and molybdenum<sup>3</sup> has been determined to be a [110] direction parallel to the wire axis. The purpose of this study is to extend the available information on body-centered cubic wire textures to other metals and alloys.

Wires were produced using hand wire rolls and dies as given in Table I. In addition, attempts were unsuccessful to draw wires from chromium, vanadium (Vanadium Corp. of America), and tungsten (Cleveland Tungsten Inc.). Although it is known that wires can be made from these materials, suitable techniques were not readily adaptable.

Where necessary, wires were polished and etched to form flat ribbons 0.005 to 0.007 in. thick, and transmission X-ray patterns were taken using molybdenum radiation with the specimen tilted 0 degrees from the perpendicular toward the beam to critically cover the wire axis. Analyses were made of (110), (002), and (112) reflection circles.

Table I. Wires Used in Study

|------------------------------|----------------------------|-------------------------------|-------------------------------------------------------|
| $\beta$ brass<br>(51.92 pct) | American Brass Co.         | 78.1                          | Hot worked at 600°C                                   |
| $\beta$ brass<br>(62.5 pct)  | Scovill Mfg. Co.           | 71.2                          | Quenched from 875°C,<br>Cold formed                   |
| Iron                         | Armco                      | 97                            | Cold formed                                           |
| Molybdenum                   | North American<br>Phillips | 93                            | Hot formed starting at<br>550°C, finished at<br>110°C |
| Niobium                      | Rem-Cru                    | 95                            | Cold formed                                           |
| Tantalum                     | Fansteel                   | 97                            | Cold formed                                           |

In all cases reflection maxima indicated the texture to be a single [110] deformation fiber, as illustrated by Fig. 1 for molybdenum. In the case of the hot-worked  $\beta$  brass, a second texture, [100], was also found, but this is believed to be the result of recrystallization since it has been reported for recrystallized molybdenum wires<sup>4</sup> and it was not present in the cold-drawn  $\beta$  brass. The difference

Fig. 1—Molybdenum wire drawn 93 pct reduction in diam.

Wire axis verticle tilted 10° from perpendicular toward the beam. (110) ring shows maxima at 0°, 60°, and 90° from wire axis, (002) ring at 45° and 90°, and (112) ring at 30°, 55°, 73° and 90° indicating a single [110] texture.

in drawability between the 51.92 pct Cu  $\beta$  brass and the 62.5 pct Cu  $\beta$  brass (containing some grain boundary  $\alpha$  due to incomplete quenching) is quite striking, since the latter could be cold worked readily while the former had to be hot worked to avoid cracking.

### Summary

The deformation texture of drawn body-centered cubic wires of  $\beta$  brass, iron, molybdenum, niobium, and tantalum is essentially a single [110] fiber as predicted by theory.<sup>5</sup>

# Rapid Tempering of High Speed Steel

by A. E. Powers and J. F. Libsch

THE simultaneous influence of time and temperature upon the tempering process in steel is well known. Hollomon and Jaffe<sup>1</sup> have expressed the effect of time and temperature upon the progress of tempering by a single parameter,  $T (c + \log t)$ ; where  $T$  is the absolute temperature;  $t$ , the tempering time; and  $c$ , a constant characteristic of the steel and treatment. It was found that when hardness data for plain carbon and low alloy steels were plotted vs. this parameter, a master tempering curve was obtained which satisfied all the data for a given steel and a given hardening treatment. Roberts, Grobe, and Moersch<sup>2</sup> successfully applied the tempering parameter to various tool steels, including high speed steel for tempering times ranging from 6 min to 100 hr. The influence of tempering time and temperature upon the physical properties of high speed steel has also been extensively investigated.<sup>2-5</sup>

Recently, the use of induction heating for very rapid tempering treatments has received attention. The authors<sup>6</sup> have shown that tempering treatments of only a few seconds duration may be successfully applied to plain carbon and low alloy steel. However, the influence of such short tempering treatments in high speed steel has not been explored.

Since high speed steel is a highly alloyed steel exhibiting physical reactions during tempering that are often relatively slow and large in magnitude, it is an interesting steel for the study of tempering reactions. It was the purpose of the present investigation, therefore, to study the early progress of reactions leading to secondary hardness in high speed steel, type 6-5-4-2, and to determine if induction-tempering treatments of a few seconds duration are able to produce results equal to those of more conventional long-time tempering cycles.

## Experimental Details

The chemical compositions for two different heats of W-Mo high speed steel used in this study are given in Table I.

Table II summarizes the heat treatment given various groups of specimens cut  $2\frac{1}{2}$  in. long and centerless ground to  $\frac{1}{4}$  in. diam. Hardening treatments consisted of preheating to 1600°F (870°C) for  $\frac{1}{2}$  hr and then oil quenching from 2250°F (1230°C). Heat I was subjected to the high temperature in a salt bath for 3 min, while specimens of heat II were austenitized in a carbon-block muffle furnace for 10 min. Specimens of series E were

\* Oil quenched from 2250°F.

immediately refrigerated to -318°F (-195°C) in liquid nitrogen following the hardening treatment to transform the major portion of the retained austenite. Specimens of series F and G were subzero cooled to -100°F (-75°C) in a dry ice-alcohol mixture.

Induction tempering was performed with a Lepel high frequency converter operating at a frequency of approximately 300,000 cycles per sec. Heating cycles were controlled and recorded for each specimen using a chromel-alumel thermocouple, percussion welded to the surface of the specimen, and a modified high speed instrument with a timer previously used and described.<sup>7</sup> Temperature oscillation of the specimens, while being held at the tempering temperature, was  $\pm 15^\circ\text{F}$  ( $8^\circ\text{C}$ ).

**Tempering Treatments:** After hardening, specimens were tempered between 900° and 1500°F (480° and 815°C) to study the progress of retained austenite decomposition and secondary hardening. The specimens tempered in salt for 1 hr (series C, G, and I) were considered to represent conventional treatment and are used for comparison with rapid tempering treatments. Several induction-tempering cycles were employed: 1—flash tempering, i.e., induction heating to the tempering temperature and immediately cooling (series A, E, and F); 2—induction heating for 60 sec at temperature (series B); and 3—double-induction tempering by two successive heating and cooling cycles (series D). All specimens tempered by induction were heated at an initial rate of 450°F (250°C) per sec except those of series E, which were heated at an initial rate of 1300°F

Fig. 1—Representative temperature-time curves for induction-heated and lead bath-heated specimens.

(720°C) per sec. Finally, one series of specimens (series H) was tempered by heating in a lead bath for a total time of 10 sec to determine the possible influence of high frequency induced energy upon the rate of tempering by comparison of lead and induction-tempered samples. All specimens were air-cooled from the tempering temperature.

Fig. 1 shows typical heating and cooling curves for specimens tempered in lead, and by induction, using initial heating rates of 1300°F (720°C) and 450°F (250°C) per sec. Specimens induction tempered for 60 sec were heated at an initial rate of 450°F (250°C) per sec and held at temperature by power impulses from the converter.

With very rapid tempering treatments involving little or no time at the tempering temperature, the degree of tempering which may take place during heating and cooling may assume significant proportions. Accordingly, effective times at temperature were calculated from the recorded heating and cooling curves for the specimens tempered by induction and in lead using the step-by-step integration method proposed by Hollomon and Jaffe.<sup>1</sup> This

Fig. 2—Hardness and specific volume vs. temperature for various tempering cycles, series A, B, and C.

method utilizes the incremental equation:

$$P = T \log \left( \frac{\Delta t}{t_0} + 10^{P_s/T} \right) \quad [1]$$

where  $P$  is the value of the tempering parameter;  $T$ , the absolute temperature, °Rankine;  $\Delta t$ , an increment of time;  $t_0$ , the constant ( $10^{-12.5}$  for the steel used in this investigation); and  $P_s$ , the value of  $P$  at the beginning of the interval  $\Delta t$ .

The value of  $P$  for any tempering cycle may be found from this equation by integrating step-by-step over suitable intervals of time from the beginning of the cycle to the end. From the value of  $P$  thus obtained, and the basic relation  $P = T (c + \log t)$ , the effective time  $t$  at a given temperature  $T$  can be calculated. In the induction-heating cycles used in this study, it was found that the tempering which occurred at more than 40°F (22°C) below the tempering temperature could be neglected in the calculation of the total value of  $P$ . The effective tempering times at temperature as thus determined varied from 4.2 sec at 1500°F (815°C) to 9.0 sec at 900°F (480°C) for the specimens tempered by induction heating; and from 7.0 sec at 1500°F (815°C) to 12.0 sec at 900°F (480°C) for the specimens heated in lead. The proper effective tempering times were utilized in plotting the data obtained.

**Physical Testing:** After tempering, all specimens were centerless ground to remove approximately 0.004 in. from the surface, polished to remove grinding marks and then tested to determine specific volume and Rockwell C hardness. Specimens of series A, B, C, D, F, and G were subsequently fractured in the bend test.

Specific volume measurements were made by the weight-in-air, weight-in-water method, and all precautions were observed to insure maximum accuracy. Weighing was conducted to the nearest 0.2 mg and the temperature was measured to the nearest 0.1°C.

Bend tests were performed on 1/4 in. diam specimens in an enclosed bend-test fixture having supports 2 in. apart and a loading plunger with a 3/8 in.

Fig. 3—Hardness and specific volume vs. temperature for various tempering cycles, series C and D.

Fig. 4—Hardness and specific volume vs. temperature for various tempering cycles, series E, F, and G.

flat section contacting the specimen, so that upon application of load a 2-point loading system is affected. In comparison with rectangular specimens of similar size, the round specimens have a lower production cost and provide greater plastic deformation. Load deflection curves were constructed from simultaneous readings of load and deflection. From such curves were obtained the proportional limit or stress where the load deflection curve deviates from a straight line and the bend strength or stress at the breaking load.

### Results

**Hardness and Specific Volume:** The hardness and specific volume are plotted as a function of tempering temperature for various tempering treatments in Figs. 2, 3, 4 and 5. The specific volume curves indicate the progress of retained austenite transformation while the hardness curves show the development of secondary hardness. It is interesting to note from the figures that the progress of secondary hardening and retained austenite decomposition is similar for the induction and salt-bath tempered specimens. Essentially the same peak hardness and final specific volume are obtained for all treatments.

In Figs. 6 and 7, the hardness and specific volume data are replotted as a function of the tempering parameter,  $T$  ( $12.5 + \log t$ ). The value of 12.5 for  $c$  was selected after considering the tempering data of Roberts, Grobe, and Moersch<sup>2</sup> for the same type of steel. For comparison, the master tempering curve for hardness obtained by Roberts, Grobe, and Moersch for type 6-5-4-2 high speed steel, hardened at 2175°F (1190°C), is shown in Fig. 6.

The outstanding aspect of the master tempering curves shown in Figs. 6 and 7 is the failure of the curves representing short-time tempering treatments to coincide with the 1-hr tempering treatment. In this connection, it is important to note that the data obtained by tempering for 1 hr in salt (series C) agree reasonably well with the master tempering

Fig. 5—Hardness and specific volume vs. temperature for various tempering cycles, series H and I.

curve presented by Roberts, Grobe, and Moersch.<sup>2</sup> Whereas previous experimental work has shown that hardness data for a given steel and hardening treatment could be combined into one master tempering curve when plotted against the parameter  $T$  ( $c + \log t$ ), the present experiments indicate that a sizable discrepancy occurs when high speed steel is tempered for a total time of 1 min or less using the rapid heating rates produced by induction heating.

Since the hardness and specific volume curves of the rapidly tempered specimens are displaced to the left of the 1-hr curves, it appears that the short-time tempered specimens have responded to tempering at a rate considerably faster than that predicted by previous work. The acceleration of tempering by the rapid tempering treatments allows a decrease of 170°F (95°C) in the predicted tempering temperature, or a decrease of 240 sec from the predicted tempering time. The acceleration of 240 sec in tempering times compares with an effective tempering time of about 8 sec. This acceleration is of considerable magnitude.

**Physical Properties:** The variation in bend strength and in the proportional limit with tempering temperature for several tempering treatments is summarized in Figs. 8, 9 and 10.

In general, short-time tempering treatments appear to yield bend strength properties which are similar to those produced by the 1-hr treatment. Analysis of bend test results and the hardness and specific volume data, presented in Figs. 2, 3, 4 and 5, indicates that the maximum bend strength occurs approximately 100°F (55°C) above the temperature for maximum secondary hardness and coincides approximately with the tempering temperature providing maximum specific volume in all instances except that of double tempering by induction. It has been found by Bishop and Cohen<sup>8</sup> that maximum hot hardness also coincides with the completion of retained austenite transformation. This degree of

Fig. 6—Hardness and specific volume as a function of the tempering parameter  $T (12.5 + \log t)$ , series A through E.

tempering is usually utilized in practical applications.

The physical properties representing double tempering by induction (series D) show the effect of retempering martensite formed upon cooling from the first tempering treatment. The rather sharp peak in bend strength exhibited by specimens rapidly tempered (series A) is leveled off moderately by the double tempering treatment.

An unusual feature of the bend-test results is the high values of bend strength and proportional limit. Zmeskal<sup>9</sup> has also reported high values of bend strength for round specimens of high speed steel

Fig. 7—Hardness and specific volume as a function of the tempering parameter  $T (12.5 + \log t)$ , series F through I.

and has remarked that they are higher than those for rectangular cross-sectioned specimens. It is suggested that this may be due to stress concentration developed at corners of the latter specimens.

An evaluation of the modulus of elasticity was made using the measured values of load and deflection and was found to average  $31.0 \times 10^6 \pm 1 \times 10^6$  psi. This compares with the value of  $32.0 \times 10^6 \pm 0.5 \times 10^6$  psi obtained by Grobe and Roberts<sup>5</sup> for 18-4-1 type high speed steel.

### Discussion

An analysis of the results indicates that W-Mo type high speed steel is capable of successful response to very rapid tempering cycles. Maximum hardness and strength values have been obtained with induction-tempering cycles, which appear similar to those resulting from conventional tempering treatments. As expected, the tempering temperature for maximum hardness and strength is shifted to higher temperatures.

As mentioned previously, however, the tempering reactions appear to be accelerated by induction-tempering treatments to rates considerably greater than those predicted by the parameter  $T (c + \log t)$ . In this connection a number of possible explanations have been considered.

Fig. 8—Influence of various tempering treatments upon bend strength and proportional limit, series A and B.

**Influence of High Frequency Current:** It has been proposed<sup>10</sup> that the very high amperage currents induced in steel heated by induction may accelerate metallurgical reactions by localized heating in the metal. It appears conceivable that such a phenomenon might promote more rapid tempering. To evaluate this supposition, series H of specimens was tempered in a lead bath to maintain a relatively high rate of heating but to eliminate the influence of high frequency current.

The results, plotted in Fig. 7, indicate that induced currents are not responsible for the increased rate of tempering exhibited by the induction-tempered specimens. A comparison of the tempering curves for specimens tempered in lead, series H, and those tempered in salt for 1 hr, series I, shows that the curves still lack coincidence, although to a smaller degree. Since a study of the heating and cooling curves for the specimens heated in lead and by induction (Fig. 1) indicates the primary difference in treatment to be in the heating rate, the discrepancy between the induction and lead-bath heated specimens is attributed to the difference in heating rate as discussed below. It is believed that this result

adds further confirmation to the work of J. G. Kerr,<sup>11</sup> who concluded that induction heating did not accelerate the solution of carbides by localized heating on a microscopic scale.

**Influence of Heating Rate:** The rate of heating appears to provide the most satisfactory explanation for the acceleration in the rate of tempering associated with short-tempering treatments. The specimens tempered by induction are characterized by their rapid rates of heating in addition to the short tempering time. The rate of heating which appears most important is the rate at which the specimen approaches the tempering temperature. In this respect, the specimens tempered in lead exhibit a considerably slower heating rate. It is believed significant that the tempering curve for specimens tempered in lead, employing a heating rate less than that of induction but greater than that in salt, occupies an intermediate position in Fig. 7.

**Theoretical Treatment:** It is proposed that plastic deformation or thermal strain caused by very rapid heating to the tempering temperature is responsible for the deviation of the induction-tempered specimens from the master tempering curve. Such plastic strain is thought to accelerate the tempering reac-

Fig. 9—Influence of various tempering treatments upon bend strength and proportional limit, series C and D.

tions during heating and to place the steel in an advanced state of tempering at the instant the tempering temperature is reached.

This behavior is illustrated in Fig. 11 where an example is given of the progress of tempering in a specimen tempered at 1025°F (550°C). The solid line represents the progress of tempering as a function of the effective tempering time for a tempering treatment, which conforms to the ideal parameter  $T$  ( $c + \log t$ ). The parameter  $P$  in this study is defined as a measure of the actual degree of tempering as represented by hardness and specific volume.

The values of  $P$  experimentally determined for various tempering cycles are plotted in Fig. 11. It will be noted that while the point representing a 1-hr tempering treatment lies on the master tempering curve, the points representing short-time tempering lie considerably above the solid line, as

\* The theoretical value of the tempering parameter at the end of a very rapid heating curve may be calculated by subdividing the curve into smaller and smaller intervals of time and graphically integrating the equation  $P = T \log \left( \frac{\Delta t}{t_0} + 10^{P_0/T} \right)$  interval by

interval from the beginning to the end of the heating curve for each size of the subdivisions. As the intervals become smaller and more numerous, the value of the tempering parameter will approach asymptotically the correct value. As a practical short-cut, only the upper third or fourth of the heating curve may be used for each series of calculations.

Fig. 10—Influence of various tempering treatments upon bend strength and proportional limit, series F and G.

might be expected since rapid tempering has yielded accelerated results.

The broken curve in Fig. 11 is an application of the equation,  $P = T \log \left( \frac{\Delta t}{t_0} + 10^{P_0/T} \right)$  using the

value of  $P$  for the experimentally obtained 8.8-sec, induction-tempering point as a starting value of  $P_0$ . When the curve is extended forward by the step-by-step integration method, it gradually merges into the master tempering curve. Extending the broken curve to shorter times reveals the interesting inference that specimens induction tempered at 1025°F (550°C) reached the tempering temperature with an initial value for  $P$  of approximately 22,500. This value represents an advanced state of tempering which will not significantly further progress until approximately 60 sec have elapsed. The calculated value of the tempering parameter for the induction-tempered specimen (heating rate equals 450°F per sec) at the instant it attains the tempering temperature was determined from a recorded heating curve to be only 17,500.\*

**Influence of Plastic Strain:** The suggested cause for the initially advanced state of tempering at the instant the steel reaches the tempering temperature after very rapid heating is that rapid heating rates introduce plastic strains which accelerate the tempering reactions.

Two principal processes occur during the tempering of high speed steel: 1—the nucleation and growth of carbides, and 2—the conditioning of the retained austenite for its subsequent transformation upon cooling to room temperature. Averbach<sup>12</sup> has

Fig. 11—Experimental and theoretical variation of tempering parameter  $P$  with effective tempering time at 1025°F.

Fig. 12—Log effective tempering time vs.  $1/T$  for high speed steel given various tempering treatments.

given a literature review of the effect of plastic deformation on diffusion reactions, i.e., those reactions which proceed by the mechanism of nucleation and growth. It was found that the velocity of aging processes is invariably increased by plastic strain after solution heat treatment, but not by elastic strains. This is thought to be due principally to the increased rate of nucleation along the slip planes.

Nabarro,<sup>18</sup> discussing the relation of strain, diffusion, and precipitation, cites a number of references which conclude that plastic strain accelerates nucleation and growth processes. Of particular interest perhaps is an indication that diffusion may be very rapid while plastic deformation is actually in progress. Such a condition may prevail when specimens are heated with extreme rapidity to the tempering temperature by induction.

It should be understood that the plastic strain must be present during the nucleation and growth processes. If such a process takes place above the temperature of recovery and recrystallization, any prior strains will be largely removed by the time the heat-treating temperature is reached. For this reason the work of Fisher and MacGregor<sup>14</sup> hardly proves their contention that "the rate of tempering does not change in the presence of strain." Further, the results of the present work disagree with their statement that "the tempering parameter  $P$  uniquely fixes the degree of tempering . . . even when tempering proceeds in the presence of . . . strain, strain rate and stress." When plastic strain is present during tempering, it is believed the tempering reactions will be accelerated. If plastic straining occurs during the heating part of the tempering cycle, then the tempering reactions may be accelerated to an advanced state by the time the tempering temperature is reached. If an aging process occurs below the recrystallization temperature, as in many age-hardening alloys, then prior strain will mark-

edly influence the rate of aging,<sup>15</sup> since the effect of strain is only slowly dissipated.

That plastic strain immediately above the  $M_s$  point induces transformation of retained austenite is also well known. Averbach, Kulin, and Cohen<sup>16</sup> have found that the rate of the martensite reaction from the austenite is also a function of plastic strain and not of elastic strain. Jepson and Thompson<sup>17</sup> found that a stress of 10 tons per sq in. will approximately double the rate of transformation of austenite to bainite in a plain carbon steel. They noted also that transformation appeared to occur preferentially on planes of maximum shear stress.

Thus it appears from the literature that plastic strain may also accelerate the conditioning process in retained austenite during tempering of high speed steel. If the martensitic reaction is considered a nucleation and shear mechanism,<sup>18,19</sup> it may be reasoned that thermal strain will increase within the retained austenite the number and size of alloy carbides and also the number of the carbide embryo and the number of the martensitic embryo which Cohen, Machlin, and Paranjpe<sup>20</sup> have postulated to be strain embryo or dislocations.

Returning again to Fig. 11, it can be seen that the induction-tempering treatments with both heating rates of 450° and 1300°F (250° and 720°C) per sec produce about the same deviation from the ideal curve. Apparently these two heating rates produce similar accelerating effects.

The dashed curve in Fig. 11 represents the course of tempering with time which a steel should take as it is held exactly at 1025°F (550°C) after attaining the initially advanced state of tempering of  $P = 22,500$ . The point representing the double induction-tempering treatment lies slightly above this line, suggesting that the double heatings accelerated the tempering reactions to a slightly greater extent than the single heating. The point representing the 60-sec tempering treatment shows the greatest deviation from the dashed line. It appears that accelerated tempering took place during the 60 sec at temperature. Actually, specimens of this series were held at temperature by oscillating  $\pm 15^\circ\text{F}$  ( $8^\circ\text{C}$ ) about the tempering temperature for a total of about 20 times. It is thought that the power impulses produced enough thermal strain to advance the state of tempering from that represented by the single induction-tempering point to that of the 60-sec point. The point representing the lead-bath tempering treatment lies below the dashed curve as can be expected, since the final heating rate was considerably less than the heating rates for induction heating.

In the absence of the effect of thermal straining, the double-induction treatments and the 60-sec treatments should produce no significant advancement of the state of tempering over that produced by the single-induction treatment; however, the double-induction and 60-sec curves in Figs. 2 and 3 illustrate again the magnitude of the acceleration by their displacement from the curves representing single-induction tempering.

**Maximum Secondary Hardness:** Fig. 12 is a plot of  $\log t$  vs.  $1/T$  for the state of maximum secondary hardness. The solid straight line is the master tempering curve for the peak hardness and the points show the actual time and temperature experimentally found to attain peak hardness for various tempering cycles. The dashed curve is drawn to show the probable experimental relation between time and temperature for specimens which are heated

rapidly by induction and held steadily for the proper lengths of time to yield maximum secondary hardness. It is, in other words, the locus of time-temperature points for maximum secondary hardness in specimens heated rapidly by induction and held at temperature without oscillation. It can be seen that, under such conditions of heating, maximum secondary hardness should not occur at above 1150°F (620°C), regardless of the tempering time. It is important to note that the maximum secondary hardness for the 60-sec induction treatment and the double-induction treatment requires temperatures considerably less than the single-induction treatment. It is interesting to notice also that maximum secondary hardness, for a 60-sec oscillating cycle, occurs at about the same temperature as it does for the 1-hr salt-bath treatment.

Examination of Figs. 2 to 5 shows that there is a slight difference in orientation between the hardness curves and the specific volume curves when the induction-tempering curves are compared with the 1-hr curves. The relative positions of the specific volume curves with respect to the hardness curves in Figs. 2 to 5 indicate that the effect of induction-heating treatments in accelerating the transformation of retained austenite is slightly less than in the development of secondary hardness. This may indicate that the effect of thermal strain is slightly less in the transformation of retained austenite than in nucleation and growth of carbides.

The magnitude of the maximum secondary hardness for the induction-tempered specimens was found to be about one-half point Rockwell C below that of the specimens tempered 1 hr. This may be due to a greater amount of retained austenite in the induction-tempered specimens.

### Summary

1—Rapid induction tempering of W-Mo high speed steel produces mechanical properties, as indicated by hardness and bend test results, which are approximately equal to those resulting from conventional long-time tempering treatments.

2—Short-time tempering data for high speed steel exhibits a lack of conformance to the tempering parameter  $T(c + \log t)$ . It appears that tempering reactions are accelerated by rapid induction tempering to rates considerably greater than those predicted by the parameter. Plastic deformation or thermal strain during the heating part of the short tempering cycle is thought to be the cause of the tempering anomaly. It is believed that such strain accelerates the tempering reactions during rapid heating so as to place the steel in an advanced state of tempering at the instant the tempering temperature is reached. This advanced state will not proceed significantly until after a period of time depending on the extent of advancement. Induction-tempered, high speed steel which is held at the tempering temperature by short power impulses is found to undergo additional acceleration of the tempering reactions during the holding period. This is thought to be due to small thermal strain produced by the temperature oscillations. By this method of tempering maximum secondary hardness may be reached in at least a few minutes at a temperature which would normally require 1 hr by conventional methods.

3—At maximum secondary hardness, high speed steel which is induction tempered by rapid heating exhibits a slightly greater proportion of retained

austenite than does the steel which is conventionally tempered for long times.

4—Maximum bend strength for high speed steel whether tempered rapidly by induction or slowly by salt bath approximately coincides with the completion of the retained austenite transformation.

### Acknowledgments

The authors wish to express their appreciation to the Lepel High Frequency Laboratories, Inc., New York, for the induction heating equipment and for sponsorship of the research project. It is a pleasure also to thank the General Electric Co. for the bend test fixture and the Fritz Laboratory of Lehigh University for their cooperation.

# Intermediate Phases in Ternary Alloy Systems Of Transition Elements

by Sheldon Rideout, W. D. Manly, E. L. Kamen,

B. S. Lement, and Paul A. Beck

The 1200°C isothermal sections of the following ternary phase diagrams were investigated: Cr-Co-Ni, Cr-Co-Fe, Cr-Co-Mo, and Cr-Ni-Mo. In all these systems the  $\sigma$  phase was found to form extended solid solutions. Two new ternary phases of unknown structure were identified. The existence range of intermediate phases of transition elements was correlated with 3d electron vacancy concentrations.

THE occurrence of extensive ternary  $\sigma$  solid solutions in the Cr-Co-Ni and in the Cr-Co-Fe systems was described in a brief note.<sup>1</sup> More recently  $\sigma$  solid solutions were also found in the Cr-Fe-Mo system by two independent groups of investigators.<sup>2,3</sup> The existence of binary  $\sigma$  phases in the V-Co and V-Ni systems, predicted in ref. 1, was experimentally discovered recently by Duwez and Baen<sup>4</sup> and independently by W. B. Pearson, J. W. Christian, and W. Hume-Rothery.<sup>5</sup> Duwez and Baen stated two general conditions for the occurrence of the  $\sigma$  phase in alloys of the transition elements: "(1) The atomic diameters of the two metals do not differ by more than 8 per cent. (2) One of the two metals has a body-centered cubic structure while the other is face-centered cubic, at least in one of its allotropic forms."

In the course of an extensive research program conducted at this Laboratory under the sponsorship of the NACA, several ternary systems, containing  $\sigma$  solid solutions and also certain new ternary phases, were investigated. The present report describes the investigated portions of the 1200°C isothermal sections of the following ternary phase diagrams: Cr-

Co-Ni, Cr-Co-Fe, Cr-Co-Mo, and Cr-Ni-Mo. It was found that the range of existence of the  $\sigma$  phase in these four ternary systems, as well as in one of two ternary systems which were investigated by others, can be fairly consistently described in terms of electron vacancy concentrations. This supports the suggestion of Sully and Heal<sup>6</sup> that the  $\sigma$  phase is an electron compound.

## Experimental Procedure

The ternary alloys were prepared by vacuum induction melting in zirconia and alumina crucibles. Lot analyses of the metals used are given in Table I.

Specimens of all alloys were annealed at 1200°C in an atmosphere of purified 92 pct helium and 8 pct hydrogen mixture. Alloys consisting mainly of

Discussion on this paper, TP 3120E, may be sent, 2 copies, to AIME by December 1, 1951. Manuscript, April 16, 1951. Detroit Meeting, October 1951.

Fig. 1—Isothermal section at 1200°C of the Cr-Co-Ni ternary phase diagram. Alpha phase is face-centered cubic. Epsilon phase is body-centered cubic. Sigma has a complex tetragonal structure.

the face-centered cubic  $\alpha$  phase were double-forged, with intermediate annealing. The double-forged specimens were final annealed for 90 hr at 1200°C and then quenched in cold water. Alloys containing appreciable amounts of any of the other phases could not be forged. Such specimens were annealed for 150 hr at 1200°C and then quenched in cold water. Microscopic specimens of all alloys were prepared by mechanical polishing, in many cases followed by electrolytic polishing. Details of the electrolytic polishing and of the etching procedures used are being published in three NACA Technical Reports, which will also tabulate the intended compositions of the large number of alloys prepared. Many of the alloys were analyzed chemically and, in general, the results are in excellent agreement with the intended compositions.

X-ray diffraction specimens were prepared by filing or crushing the homogenized alloys, and by reannealing the obtained powders in evacuated and sealed quartz tubes. After annealing for 30 min at 1200°C, the tubes were quenched into cold water. X-ray diffraction patterns were made with unfiltered chromium radiation at 30 kv, using an asymmetrical focusing camera of high dispersion. X-ray diffraction in conjunction with microscopic study was used to identify the phases present in each specimen. The amount of each phase was estimated microscopically. The results were used to construct 1200°C isothermal sections of the various ternary phase diagrams. The accuracy of the location of the phase boundaries determined in this manner is estimated to about  $\pm 1$  pct of each component.

### Results

The results of the experimental work are shown in Figs. 1 to 4. It is seen that the  $\sigma$  phase tends to form narrow, extended fields. In the Cr-Co-Ni, Cr-Co-Mo systems this narrow elongated ternary  $\sigma$  phase field is connected with the binary Cr-Co  $\sigma$  phase. The composition range of the latter at 1200°C was found to be about 58 to 60 pct Cr, that is, shifted toward higher Cr contents in comparison with previously reported values.<sup>7</sup> It is significant that in the Cr-Co-Ni and Cr-Co-Fe systems the  $\sigma$  phase extends in a direction corresponding to approximately constant Cr content, indicating that Ni and Fe are capable of partially replacing Co in forming the  $\sigma$  phase. On the other hand, in the Cr-Co-Mo system the  $\sigma$  phase extends in a direction corresponding to approximately constant Co content. This indicates that molybdenum is replac-

ing chromium in forming the  $\sigma$  phase. It is interesting that in the Cr-Ni-Mo ternary system, Fig. 4, the  $\sigma$  phase occurs as a ternary phase; none of the binary systems involved are known to have a  $\sigma$  phase at any temperature. Here too, molybdenum appears to replace chromium in forming the  $\sigma$  phase.

Some exploratory work was done on the Cr-Co-Fe system at 800°C, a temperature where the Cr-Fe binary  $\sigma$  phase exists. It was found that the  $\sigma$  phase field extends continuously from the Cr-Co binary phase to the Cr-Fe binary phase, straight across the ternary system. Fig. 5 shows the  $\sigma$  phase field in the Cr-Co-Fe system at both 1200°C and 800°C. The analogy of the Cr-Co-Ni and the Cr-Co-Fe systems at 1200°C suggests that in the Cr-Co-Ni system at some temperature lower than 1200°C the  $\sigma$  phase might also extend all the way to the Cr-Ni binary system. The fact that none of the previous investigations of this binary system revealed the existence of the  $\sigma$  phase might then be explained on the basis that in the temperature range in which the hypothetical Cr-Ni binary  $\sigma$  phase is stable the rate of diffusion is so low that no appreciable amounts can form in practical periods of annealing. In the course of the present work, several attempts were made to verify this hypothesis, without success. If such a binary phase exists, it is apparently unstable at 500°C and above.

The hexagonal phase designated by  $\mu$  in Fig. 3 was previously known in the Co-Mo binary system<sup>8</sup> as  $\epsilon$ . The new nomenclature was adopted in order to eliminate confusion with the body-centered cubic  $\epsilon$  phase at the Cr end of the Cr-Co system.<sup>7</sup>

As shown in Figs. 3 and 4, new ternary phases were found in the Cr-Co-Mo and Cr-Ni-Mo systems, designated as R and P respectively. The crystal structure of these phases is not known. Table II gives the computed  $d$  values and the estimated relative intensities of their principal X-ray diffraction lines. Both of these phases are very hard. As judged by its tendency to shatter, the P phase appears to be

Fig. 2—Isothermal section at 1200°C of the Cr-Co-Fe ternary phase diagram. Phases as in Fig. 1.

Fig. 3—Isothermal section at 1200°C of a portion of the Cr-Co-Mo ternary phase diagram. The structure of the new ternary R-phase is unknown.

almost as brittle as the  $\sigma$  phase, but the R phase is distinctly less brittle.

Based on Pauling's data for the distribution of valence electrons between cohesive and atomic orbitals in transition elements, a correlation has been found in the above alloy systems between the composition range of the  $\sigma$  phase field and the concentration of electron vacancies in the 3-d subband. Pauling,<sup>9</sup> gives the following numbers for the electron vacancies per atom in the 3-d subband of the various transition elements of the third period: Cr, 4.66; Mn, 3.66; Fe, 2.66; Co, 1.71; and Ni, 0.61.

Assuming that these electron vacancy values are valid for the transition elements in their alloys with each other, the average electron vacancy concentration in single phase alloys of these elements,  $N_v$ , can be calculated according to the following formula:

$$N_v = 4.66(\text{Cr}) + 3.66(\text{Mn}) + 2.66(\text{Fe}) + 1.71(\text{Co}) + 0.61(\text{Ni}) \quad [1]$$

where the symbols (Cr), (Mn), etc., stand for the atomic fractions of the corresponding elements in the alloy.

The electron vacancy concentration in the 4-d subband of molybdenum is not known. Since molybdenum is a transition element following chromium in the same column of the periodic table, it might be assumed that  $N_v$  for the 4-d subband of molybdenum equals that for the 3-d subband of chromium. On this basis, the following formula may be used for molybdenum containing alloys:

$$N_v = 4.66(\text{Cr} + \text{Mo}) + 3.66(\text{Mn}) + 2.66(\text{Fe}) + 1.71(\text{Co}) + 0.61(\text{Ni}) \quad [2]$$

Fig. 6 shows the range of the  $\sigma$  phase field in the 1200°C isothermal sections in the ternary systems studied, and in the systems Cr-Ni-Fe<sup>10</sup> and Cr-Mo-Fe,<sup>2,8</sup> with compositions plotted in atomic percentages. A series of straight and parallel "iso-vacancy" lines (solid lines), each of which represents a constant number of electron vacancies per atom, were also plotted in each diagram on the basis of formula 2.

In the ternary diagrams with molybdenum, better alignment of the elongated  $\sigma$  phase fields with the lines of constant  $N_v$  values may be achieved by assuming a value of  $N_v = 5.6$  for molybdenum. Although such a value has not been suggested on the basis of other evidence, the corresponding "iso-

vacancy" lines were included in the figure (dotted lines in Fig. 6), as calculated from the following formula:

$$N_v = 5.6(\text{Mo}) + 4.66(\text{Cr}) + 3.66(\text{Mn}) + 2.66(\text{Fe}) + 1.71(\text{Co}) + 0.61(\text{Ni}) \quad [3]$$

The composition ranges of the  $\sigma$  phase in the various ternary systems, expressed in terms of concentration of electron vacancies, are given in Table III. For the ternary systems with molybdenum, the composition ranges were calculated on the basis of both formulas 2 and 3, and both sets of values are given in the table.

These results indicate that the  $\sigma$  phase is largely limited to alloys corresponding to the approximate range of 3.36 to 3.6 electron vacancies per atom. A notable exception is the Cr-Fe-Mo system, where the upper limit of the  $N_v$  range is considerably higher. It is not impossible that equilibrium conditions were not attained in the Cr-Fe-Mo system and that the composition range of the  $\sigma$  phase may be narrower than reported. In the Cr-Co-Mo and Cr-Ni-Mo systems the values for the lower limit calculated from formula 2 are distinctly lower than those in other systems. However, better agreement is reached by using formula 3. Although electron vacancy concentrations favorable to the  $\sigma$  phase are in the range of 3.36 to 3.6, it does not follow that all alloys corresponding to this range consist at equilibrium of the  $\sigma$  phase. As postulated by Duwez and Baen, other factors, such as relative atomic size,

may be decisive in prohibiting the formation of the  $\sigma$  phase in some cases where the above electron vacancy condition is fulfilled.

The electron vacancy concentration ranges for some of the other intermediate phases present in the ternary systems surveyed are also indicated in Fig. 6. These results are summarized in Table IV. It appears that the electron vacancy concentration ranges of the various intermediate phases in the same system may overlap.

Discussion of Results

The observation that nickel, cobalt, and iron, on the one hand, and chromium and molybdenum, on the other, may partially or wholly replace each other in forming the  $\sigma$  phase provides strong additional support for the condition, formulated by Duwez and Baen<sup>4</sup> that the  $\sigma$  phase may be formed when face-centered cubic transition elements are alloyed with body-centered cubic transition elements. From the point of view of the electron vacancy concept, this condition is a result of the requirement for the formation of  $\sigma$  that intermediate electron vacancy concentrations (about 3.36 to 3.6) be attained, between those for the face-centered cubic transition elements Ni, Co, and Fe (0.6 to 2.7) and those for the body-centered cubic transition

Table III. Electron Vacancy Concentration Ranges for the Sigma Phase in Ternary Alloys.

| Ternary System             | N <sub>v</sub> Electron Vacancy Concentration |                           |
|----------------------------|-----------------------------------------------|---------------------------|
|                            | Calculated from Formula 2                     | Calculated from Formula 3 |
| Cr-Co-Ni (1200°C)          | 3.36 - 3.57                                   |                           |
| Cr-Co-Fe (1200°C)          | 3.42 - 3.57                                   |                           |
| Cr-Co-Mo (1200°C)          | 3.18 - 3.57                                   | 3.35 - 3.57               |
| Cr-Ni-Mo (1200°C)          | 3.16 - 3.5                                    | 3.47 - 3.68               |
| Cr-Fe-Ni (650°C)           | 3.51 - 3.66                                   |                           |
| Cr-Fe-Mo (650° and 1300°C) | 3.41 - 4.07                                   | 3.61 - 4.44               |

elements Cr and Mo (4.7 and possibly 5.6). Such intermediate values can be realized in alloys containing both types of transition elements. As seen in Fig. 6, the substitution rules for ternary alloys mentioned may be more sharply formulated in terms of this electron vacancy concentration requirement than in terms of atom for atom substitution of one face-centered (or similarly one body-centered) cubic transition element for another.

Since manganese has an electron vacancy number near the upper limit tolerated in the  $\sigma$  phase, it might be expected that manganese metal itself, or manganese-rich alloys with other transition elements would have favorable electron vacancy conditions to form the  $\sigma$  phase. In fact, A. R. Troiano<sup>11</sup> found that the X-ray diffraction patterns obtained for quenched specimens of a certain Mn-rich Mn-Fe alloy contained lines of the  $\sigma$  phase. It might be also expected that in Cr-Co-Mn and similar ternary systems the  $\sigma$  phase would be able to dissolve considerable quantities of manganese, thus forming extensive solid solution fields. The  $N_v$  values calculated from formula 1 of the present paper for the limits of the Cr-Mn  $\sigma$  phase given by Pearson, Christian, and Hume-Rothery in their recent paper<sup>5</sup> are 3.83 and 3.94. These values are much higher than the upper limit found for the various  $\sigma$  phases investigated in the present paper. In order to bring about agreement, manganese would have to be as-

Fig. 4—Isothermal section at 1200°C of a portion of the Cr-Ni-Mo ternary phase diagram. The structure of the new ternary P-phase is unknown.

signed a vacancy number of approximately 3.3 instead of Pauling's value of 3.66. The cause for the anomalous behavior of manganese in these alloys is not well understood.

In the Fe-V system the  $\sigma$  phase appears to extend over a considerable range of composition. The concentration limits at 700°C, as determined by Martens and Duwez<sup>13</sup> are 37 atomic pct and 57 atomic pct of vanadium. If it is assumed that the number of electron vacancies in vanadium is 4.66, as in chromium, the  $N_v$  values for the  $\sigma$  phase boundaries at 700°C are 3.29 and 3.80, respectively. The average value is quite closely the same as that for the range of 3.36 to 3.6, given above for other  $\sigma$  phases. An  $N_v$  value for vanadium similar to that for chromium is strongly suggested by the recent work of Martens and Duwez<sup>13</sup> on the V-Cr-Fe ternary system, where the  $\sigma$  phase forms a continuous series of solid solutions from the V-Fe to the Cr-Fe binary system, with the average atomic percentage of Fe remaining approximately constant from one end to the other of the series. For the recently discovered V-Co, V-Ni, and V-Mn  $\sigma$  phases the compositions given in ref. 5 and the value of  $N_v = 4.66$  for vanadium lead to the following figures:  $N_v = 3.21$  for the V-Co alloy with 50.5 atomic pct vana-

Fig. 5—The sigma phase in the Cr-Co-Fe ternary system at 1200°C (solid lines) and at 800°C (dotted lines).

Fig. 6—Survey of intermediate phases in ternary systems of transition elements, plotted in atomic percentage. Systems of straight lines represent constant electron vacancy concentrations, as indicated.

dium, 2.83 to 3.24 for the composition range of 55 to 65 atomic pct vanadium in the V-Ni system, and 3.9 for the V-Mn alloy with 24.3 atomic pct vanadium. The last mentioned figure is too high, and may be brought in line with the usual range by assigning a lower vacancy number to manganese, as suggested in the previous paragraph. Interpretation for the low figures obtained for the V-Co and V-Ni  $\sigma$  phases is at present not available.

After completion of this manuscript, a recent note by A. H. Sully<sup>12</sup> was brought to the attention of the authors. In this publication the correlation of  $\sigma$  phase boundaries with electron concentration in various binary systems is investigated. The results correspond very well with those in the present paper, if it is kept in mind that, under the assumptions made by Sully, the number of excess bonding electrons per atom,  $N_B$ , is related to the number of vacancies per atom,  $N_v$ , as follows:  $N_B = 5.78 - N_v$ . On this basis, the critical value of  $N_B = 2.25$ , found by Sully, corresponds to  $N_v = 3.53$ , which is within the range of 3.36 to 3.60 given in the present paper, and near its upper limit.

### Conclusions

1—In the Cr-Co-Ni, and Cr-Co-Fe phase diagrams at 1200°C the Cr-Co  $\sigma$  phase forms elongated

fields extending deeply into the ternary systems. The extension of the ternary solid solution fields suggests that in these systems nickel, respectively iron is capable of partially replacing cobalt in forming the  $\sigma$  phase. At 800°C the  $\sigma$  solid solution field extends all the way from the Cr-Co  $\sigma$  phase to the Cr-Fe  $\sigma$  phase across the Cr-Co-Fe ternary diagram, so that here Fe and Co are completely replacing each other.

2—In the Cr-Co-Mo system at 1200°C the Cr-Co  $\sigma$  phase forms an elongated field of ternary solid solutions suggesting that molybdenum is capable of partially replacing chromium in forming the  $\sigma$  phase.

3—In the Cr-Ni-Mo system, in which no binary  $\sigma$  phase is known to occur, at 1200°C  $\sigma$  solid solutions form a ternary phase in which chromium and molybdenum may partially replace each other.

4—The above results may be interpreted in terms of electron vacancy concentrations. A condition for the occurrence of the  $\sigma$  phase appears to be the attainment of a range of electron vacancy numbers per atom intermediate between that in the face-centered cubic transition elements, nickel, cobalt, iron, and in the body-centered cubic transition elements, chromium and molybdenum.

5—In the Cr-Co-Mo system a new ternary phase R was found in a small concentration range between the  $\sigma$  and  $\mu$  phases. In the Cr-Ni-Mo system another new ternary phase, P, was located between the  $\sigma$  and  $\delta$  phases. The X-ray diffraction pattern of R is different from that of P, and both patterns appear to be different from those of all known phases in alloys of the transition elements.

# Oxidation of Titanium

by M. H. Davies and C. E. Birchenall

The rate of oxidation of titanium in the temperature range 650° to 950°C has been measured. The linear rate law obtained is explained by interface reaction control of the process. Tracer experiments indicate the oxygen diffuses in at least one phase of the scale.

THE kinetics of oxidation of titanium, principally at low temperatures and under varying oxygen pressures, have been reported.<sup>1, 2</sup> In the present investigation the rates of oxidation of titanium have been determined by the gravimetric method in the temperature range 650° to 1000°C under 1 atm of oxygen. Some of the scales formed were powdered and an endeavor was made to identify the phases present by X-ray diffraction.

Alexander and Pigeon<sup>1</sup> ascribe a logarithmic rate law to the growth of thick films formed at temperatures up to 565°C, and Gulbransen and Andrew<sup>2</sup> suggest that the parabolic rate law holds up to 600°C. In both cases large initial deviations from those relationships are apparent and no explanation is offered.

In the present experiments it is shown that a linear rate law holds in the temperature range 650° to 1000°C, and it is suggested that the initial deviations observed are due in part to a spurious surface area effect and also to the high solubility of oxygen in titanium metal. Positive information on the mechanism of oxidation is not available, but oxygen ion diffusion through the lattice is inferred from the re-

sults of trace experiments. X-ray analysis of the scale confirms Gulbransen and Hickman's<sup>3</sup> observation on the presence of rutile  $\text{TiO}_2$ .

## Experimental Details

The titanium used in these experiments was prepared by the reduction of titanium tetrachloride with magnesium and was used in the form of rolled sheet. Samples approximately 0.040x0.5x0.75 in. were cut and polished to a fineness of 4/0 on metallographic polishing papers.

Individual samples, suspended on a platinum wire, were lowered into the hot zone of a furnace, in vacuo, by means of a winch, and oxygen was admitted after the desired temperature was attained. The increase of weight of single samples oxidized for fixed times at certain temperatures was determined by weighing the sample before and after oxidation on a chemical balance. In these instances the sample was used for only one time at one temperature. In some cases the course of oxidation was followed by attaching the sample to a sensitive spring balance and noting periodically the extension of the spring with time of oxidation.

Kirkendall type experiments were carried out by marking the surface of the titanium prior to oxidation with a solution containing radioactive silver. After drying, the specimen was heated in vacuo to decompose the silver nitrate used, leaving a small amount of metallic radioactive silver on the surface. Following oxidation, these samples were mounted, ground, and then placed in intimate contact with

High purity electrolytic oxygen was used throughout these experiments to avoid the possibility of nitrogen contamination.

### Experimental Results and Discussion

The rate of gain in weight of titanium oxidized at various temperatures is plotted in Figs. 1 and 2. It can be seen that, apart from initial deviations, the amount of oxygen uptake is a linear function of time.

The reaction rate is expressed by the equation:

$$\frac{W}{A} = lt$$

where  $W$  is the gain in weight of the sample;  $A$ , the area calculated from the geometrical dimensions of the specimen;  $t$ , the time of oxidation, and  $l$ , the proportionality constant. Values of  $l$  at the temperatures studied have been obtained from the linear portions of the various isothermal curves and these are plotted in Fig. 3 as  $\ln l$  vs. the reciprocal of absolute temperature. The values at various temperatures are given in Table I. Several check runs<sup>7</sup> on iodide titanium in the range 900° to 1000°C showed no appreciable differences.

The relative densities of  $\text{TiO}_2$  which forms a considerable part of the scale and titanium metal satisfy the Pilling and Bedworth<sup>4</sup> relationship for the formation of protective scales, and it is thus surprising that a linear rate law should obtain for the oxidation of titanium.

Fig. 2—Rates of titanium oxidation between 650° and 820°C.

The initial deviations from linearity indicated in Fig. 1 are attributable to a surface area effect at least in part; that is, the true surface area exceeds, initially, the surface area calculated from the geometrical dimensions of the specimen by some roughness factor. This effect disappears when the scale attains a minimum finite thickness (which will depend upon the initial surface preparation). Some confirmation of this surface area effect is shown by the value of the  $W/A$ , the weight gain/unit surface area, at zero time obtained from extrapolation of the linear portions of the various curves. This approaches zero as the temperature is raised, Fig. 1.

There is, to the knowledge of the authors, only one other case in the literature of a linear rate law for the oxidation of metals which form a "protective" scale.\* This is for aluminum between 500° and 550°C.<sup>5</sup> Those metals which do conform to a linear rate law are reactive metals such as sodium and magnesium for which the molecular volume of the oxide is less than the molecular volume of the metal.

A complete analysis of the oxidation process with regard to titanium is made unusually complex by the exceedingly high solubility of oxygen in the metal, so that during oxidation a considerable portion of the oxygen uptake enters into solid solution in the metal. This process may contribute also to the initial deviation from linearity. In many cases, complete mechanical separation of metal and scale is possible and in one case (titanium oxidized for 100 min at 900°C) it was found that assuming the scale to be 100 pct  $\text{TiO}_2$ , then 36 pct of the total oxygen entered into solid solution in the metal.

Analysis of a sample oxidized until all metal was consumed yielded the average formula  $\text{Ti}_2\text{O}_3$  and so the value of 36 pct of total oxygen absorbed entering into solid solution is low. Since X-ray analysis of some of the scales has indicated the presence of only  $\text{TiO}_2$ , an average formula of  $\text{Ti}_2\text{O}_3$  can only be explained by the existence of a lower oxide with a wide composition range, since appreciable quantities of a lower oxide of fixed composition would yield a diffraction pattern for the amounts of lower oxide required to give the average composition observed. It is certain that the solubility of oxygen in titanium is high, but detailed information on the Ti-O system is lacking. Ehrlich<sup>6</sup> submits information on the existence of three intermediate phases of lower oxygen concentration than that required for the formation of  $\text{TiO}_2$ . These are in order of increasing oxygen concentration:

| Phase    | Type of Structure | Limits of Composition                   |
|----------|-------------------|-----------------------------------------|
| $\delta$ | NaCl              | $\text{TiO}_{0.6} - \text{TiO}_{1.25}$  |
| $\gamma$ | $\alpha$ Corundum | $\text{TiO}_{1.46} - \text{TiO}_{1.56}$ |
| $\beta$  |                   | $\text{TiO}_{1.7} - \text{TiO}_{1.8}$   |

Rutile,  $\text{TiO}_2$  is ascribed a range in composition from  $\text{TiO}_{1.9}$  to  $\text{TiO}_2$ .

Only one of the above oxides, the  $\delta$  phase, would satisfy the requirements stated previously for a scale of average composition  $\text{Ti}_2\text{O}_3$  whose X-ray diffraction pattern would yield only lines due to  $\text{TiO}_2$ . (A small amount of  $\text{Ti}_2\text{O}_3$  may be present in the scale. Thomas,<sup>7</sup> using more sensitive X-ray techniques, was able to identify the presence of this phase. A lower oxide was also indicated but not identified.)

\* The case of tungsten is not truly analogous since oxides formed on that metal grow out in blocks perpendicular to the surfaces of a parallelepiped specimen. In titanium the oxide is compact and continuous around the metal.

The linear rate law obtained for the oxidation of titanium can be explained on the basis that the process is controlled by some interface reaction, such reaction being of zero order, and it seems most likely that the controlling reaction occurs at the oxide-oxygen interface.

Were the process controlled by the reaction at the metal oxide interface, then it could be expected that the  $\alpha$  to  $\beta$  transformation in the metal would affect the reaction rate. The most recent information<sup>8</sup> on the effect of oxygen on the transition temperature of titanium, which occurs at about 880°C in the pure metal, indicates that the transition temperature is raised by the presence of oxygen in solution. With normal impurities in Kroll titanium, the transformation occurs over the range 860° to 970°C. Any tendency toward lower transformation due to impurities should be counteracted by the oxygen dissolved in the metal. A break in the rate curve, Fig. 3, is obtained at about 830°C, but this cannot be attributed to the phase transformation. Above 830°C  $\ln l$  is another linear function of  $1/T$  with no inflections observed at temperatures up to about 1000°C.

The strong dependence of the rate of oxygen uptake by titanium, during oxidation, on oxygen pressure as found by Gulbransen and Andrew<sup>1</sup> seems to support the theory of interface reaction rate control of the oxidation process. The composition of titanium oxides in equilibrium with varying pressures of oxygen is unlikely to change owing to the apparently very low dissociation pressures of those oxides, and it is thus unlikely that a diffusion controlled process (inferred by a parabolic rate law) would be dependent on oxygen pressure unless that pressure was of the order of the oxygen dissociation pressure of the oxide. On the other hand, it is probable that a surface reaction rate would be sensitive to oxygen pressure.

It can be expected that the plot of  $\ln l$  vs.  $1/T$  for such a surface reaction will yield a straight line and the apparently sharp break in this plot at 830°C cannot be fully explained. A similar occurrence observed in the oxidation of magnesium<sup>10</sup> is associated with the oxidation of that metal in the vapor phase. Oxidation proceeds by the molecular diffusion of oxygen through the oxide and subsequent reaction at the metal-oxide interface. The inflection obtained is attributed to the rapidly increasing vapor pressure of magnesium with temperature and is fully explained in the paper. It is very unlikely that a similar phenomenon obtains in titanium oxidation because of the very low vapor pressure of titanium at these temperatures.

However, a change in color of the outer oxide was noted. Scales formed at 820°C or below exhibited

Fig. 3—Plot of the logarithm of  $l$ , the linear rate constant vs. reciprocal of absolute temperature in the oxidation of titanium.

a yellow color on the outer surface whereas those formed above that temperature were orange to brown in color. Although rutile may change its color with changing oxide content, there may be a change in the nature of the outermost oxide resulting in a change in the reaction rate. The change may be due to a phase transformation in the oxide or to the appearance of a new oxide on the surface. The yellow outermost oxide may be  $\text{TiO}_3$ , but scant information is available on this oxide. It is possible that the dissociation pressure of this oxide approaches 1 atm about 830°C and the change in color and reaction rate may be attributable to this effect.

To determine the mechanism of oxidation, attempts were made to follow the movement of inert markers as in experiments by Pfeil,<sup>11</sup> Smigelskas and Kirkendall,<sup>12</sup> and da Silva and Mehl.<sup>13</sup> The marker employed in this case was radioactive silver and the autoradiographic technique was used in the endeavor to locate the marker after oxidation. Since no trace of the radioactive material was obtained, it is presumed that the silver remained at the oxide-oxygen interface and was evaporated during the appreciable times (four days) required to form thick scales at about 900°C. The silver activity employed was high enough that if it had dissolved in the metal and/or oxide, it should have been detected in the Geiger counter measurements which were tried. In similar experiments to determine the diffusing ion involved in the growth of  $\alpha\text{-Fe}_2\text{O}_3$ ,<sup>14</sup> the inert radioactive marker could not be located. Conductivity studies on this oxide confirm that the oxygen ion is mobile in the growth process. The markers in other oxides were located easily when embedded below the surface. During the growth of wüstite on iron<sup>14</sup> the platinum wires on which the samples were hung became enveloped by the growing oxide. This did not occur in the case of titanium oxidation. These results seem to indicate that diffusion of oxygen ions is responsible for the growth process, in at least the outer layer of oxide. That oxygen diffuses in  $\text{TiO}_2$  is suggested by

Table I. Values for  $l$  — the Linear Rate Constant at Various Temperatures

the composition limits for that phase given by Ehrlich which show rutile to be an oxygen deficient lattice.

A complete metallographic examination of the scales formed was not possible owing to the extremely brittle nature of the oxides.

### Summary

The results of this investigation and of a previous uncompleted investigation<sup>7</sup> show that titanium oxidized according to a linear rate law, which may be associated with the interface reaction at the oxide-oxygen interface. Slight deviations observed in the behavior of iodide-refined and "Kroll" titanium<sup>2</sup> may be attributable to the presence of impurities, and in particular the presence of hydrogen in titanium produced by the magnesium reduction of TiCl<sub>4</sub> may be responsible for those deviations observed.

The initial nonlinear relationship between oxygen uptake and time of oxidation is attributed to a spurious surface area effect and to the high solubility of oxygen in titanium metal. Rates of oxidation of titanium at various temperatures have been calculated and a reason for the inflection in the plot of  $\ln l$  vs.  $1/T$  postulated.

Experiments to determine the mechanism of oxidation indicate that the diffusion of oxide ions is involved in at least part of the scale.

It is suggested that further work on the oxidation of titanium should be preceded by accurate determination of the Ti-O phase diagram. Subsequent use of refined techniques to evaluate the nature and relative amount of the various phases in the scale should enable the calculation of data relative to their rates of formation and also to the diffusion of oxygen in the metal. In the light of the present experiments, it is unlikely that the diffusion data of Alexander and Pigeon<sup>1</sup> can be very accurate, since it seems that the simultaneous occurrence of an increase in thickness of the film and diffusion of oxygen into the metal does not permit a separation of the numbers

relative to each process from the experimental results available.

### Acknowledgments

This work was sponsored by the Office of Naval Research, whose financial assistance and permission to publish is gratefully acknowledged. The titanium was supplied by the Remington Arms Co., to whom the authors express their thanks. The radioactive silver was obtained from the Isotopes Div., U. S. Atomic Energy Commission. One of us is indebted to the Economic Cooperation Administration for a Fellowship Award. The authors also wish to express their appreciation for the helpful advice and continued interest of M. T. Simnad and R. F. Mehl.

### Correction

In the January 1951 issue, p. 64, TN 50E, *Crystallographic Angles for Magnesium, Zinc and Cadmium* by Edward I. Salkovitz: Table I contains errors in the crystallographic angles which have been pointed out by J. F. Nicholas, of the Division of Tribophysics, Commonwealth Scientific and Industrial Research Organization, University of Melbourne, Carlton, Vic., Australia. In transmitting the corrections, he commented as follows:

The accompanying table lists the corrected angles where the discrepancy is 0.2' or more. The  $c/a$  ratios used in the technical note and in the corrections are the generally accepted values measured by Jette and Foote<sup>2</sup> on very pure metals at a temperature of 25°C, but do not always agree with the values of  $c$  and  $a$  given in *Metals Handbook*, 1948 edition. An increase in the  $c/a$  ratios of at most 0.0002 will increase the angles for (HKIL) = (0001) by 0.1'.

<sup>2</sup> E. R. Jette and F. Foote: *Journal of Chemical Physics* (1935) **3**, p. 605.

Such increases can be caused by temperature rises of approximately 90°, 2°, and 3°C for magnesium, zinc, and cadmium, respectively, or by small amounts of impurity.

Corrected Values for Table I

| HKIL | hkil           | Magnesium<br>( $c/a=1.6235$ ) | Zinc<br>( $c/a=1.8563$ ) | Cadmium<br>( $c/a=1.8859$ ) |

# Systems Titanium-Molybdenum and Titanium-Columbium

by M. Hansen, E. L. Kamen, H. D. Kessler,

and D. J. McPherson

The highly reactive Ti-Mo and Ti-Cb alloys were prepared and heat treated under protective conditions. Phase diagrams were established based on micrographic and X-ray diffraction analysis and detection of incipient melting.  $\beta$  titanium forms a continuous series of solid solutions with both molybdenum and columbium, whereas these metals are only slightly soluble in the  $\alpha$  titanium modification.

**P**REVIOUS work on the Ti-Mo and Ti-Cb systems was very limited and is discussed in succeeding sections of this paper relating to the respective phase diagrams. The diagrams in the present work were determined principally by micrographic analysis, because other methods such as thermal analysis and dilatometry are not suitable, due to the low diffusion rates of these alloys in the transformation range. X-ray analysis was believed less useful than micrographic analysis because: 1—On quenching certain high titanium alloys from above their transformation range, the body-centered cubic  $\beta$  phase decomposes into acicular  $\alpha$  (hexagonal close-packed) which room temperature X-ray diffraction techniques cannot differentiate from isothermal  $\alpha$ . 2—High temperature X-ray techniques might be used, but are difficult to apply and are subject to error because of the high reactivity of titanium with gases such as oxygen and nitrogen. Although metallographic study was the basic method used, X-ray diffraction analysis was applied to a limited extent, to further substantiate the findings.

The transformation ranges on the titanium side of the Ti-Cb and Ti-Mo systems were studied both with DuPont Process A (magnesium-reduced) titanium alloys and with iodide titanium alloys. The Process A metal was used chiefly to bracket the transformation range in order to reduce the number of alloys given a particular treatment for the more accurate final study with iodide titanium alloys.

## Experimental Procedure

The analyses of the metals used in the preparation of alloys for this study are presented in Table I.

**Melting Practice:** Early in the work, a consumable electrode, arc melting furnace was used in the preparation of the Process A Ti-base Mo and Cb alloys. This type of furnace has been described by other investigators.<sup>1, 2</sup> One of the major difficulties of the consumable electrode melting process was the preparation of homogeneous electrodes (with the mixture of coarse titanium sponge and fine powder alloying addition) which would give homogeneous ingots. Composition gradients encountered may have been due to a tendency for powdered alloying metals to drop away from the electrode in handling. This difficulty in the preparation of homogeneous alloys was overcome by the use of a nonconsumable electrode furnace for later work.

This furnace is similar to the one used by McPherson and Fontana<sup>3</sup> at Ohio State University. A diagram of the nonconsumable electrode arc furnace is given elsewhere.<sup>4</sup> The source of power was a 400 amp dc welding generator.

Electrode tips of tungsten ( $\frac{1}{2}$  in. in diam) were used for all columbium melts and for a limited number of molybdenum melts. Molybdenum tips were used for the majority of molybdenum alloy melts. Columbium tipped electrodes were tried, but disintegrated rapidly at currents above 300 amp.

In the Process A titanium melting practice the metals were charged into the water-cooled spun copper crucible in the following forms: 1—titanium: sponge ( $-4+16$  mesh); 2—molybdenum: sections of 0.003 in. sheet (approximately  $\frac{1}{2}$  in. sq); and 3—columbium: powder compacts ( $\frac{1}{8}$  in. lumps broken from large section). After alternately evacuating and purging the furnace several times with argon or helium, the arc was struck against the metal charge,

M. HANSEN, Member AIME, is Assistant Chairman, and H. D. KESSLER and D. J. McPHERSON are Research Metallurgists, Metals Research Dept., Armour Research Foundation of Illinois Institute of Technology, Chicago. E. L. KAMEN is Lieutenant Junior Grade, U. S. Navy.

Discussion on this paper, TP 3148E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 16, 1951; revision, Aug. 6, 1951. Detroit Meeting, October 1951.

This paper is a condensation of the Final Report on an Air Materiel Command sponsored project, Contract No. AF33(038)-8708, E. O. No. 605-225.

Fig. 1 (left)—A 50 pct Process A Ti-Mo alloy cast and homogenized at 1250°C for 20 hr. Etchant, 1 pct HF, 3 pct HNO<sub>3</sub> in water. X250.

Fig. 2 (right)—Same alloy as Fig. 1, but without homogenization treatment.

which weighed 50 to 100 g. In general, 300 amp was applied for about 2 min, until most of the material in the crucible was melted. The current then was raised to 600 amp, and the arc so directed as to blast through the melt over the entire area covered by the molten metal. Using this blasting technique, only one or two remelts had to be made to produce a homogeneous ingot.

The iodide titanium alloy melting practice was similar to that used for Process A titanium, with the addition of several refinements. The major change for iodide titanium alloys was the adoption of a copper block crucible insert. As iodide melts ranged in size from 5 to 30 g, a smaller melting cavity was desired. Adjacent to the cavity was a tungsten insert, projecting above the level of the surface of the block. The arc was struck against the tungsten insert and then was carried over to the charge in the block cavity. With this technique, the electrode never contacted the charge and, thus, a possible source of contamination was eliminated. The iodide titanium was charged in the form of small sections cut from 1/16 in. sheet obtained by cold rolling hairpin bars.

All columbium and molybdenum alloys were

melted at least three times to achieve homogeneity. To avoid reopening the furnace and purging it, a rod was used to invert the ingot after each remelting operation. Complete dissolution of the high melting columbium and molybdenum additions in the melt was insured by radiographic inspection of samples. Helium gas at atmospheric pressure was used for all iodide melts and little or no hardness increase was obtained during the melting process.

When melting on the copper block, the current was never raised above 350 amp, as higher currents were found to cause the molten titanium alloys to wet the copper. Arc voltages of 30 to 35 v gave satisfactory arc lengths for most melting work in helium. Tungsten pickup from the tungsten tipped electrodes was generally less than 0.10 pct.

**Annealing Treatments:** Early in this investigation, it was decided to anneal all specimens in evacuated Vycor bulbs rather than in inert atmospheres, where oxygen and nitrogen contamination could possibly occur during long heat treatments. It was found that  $\beta$  solid solution samples annealed in argon were characterized by a surface layer containing  $\alpha$  phase stabilized by oxygen and/or nitrogen, whereas no contamination took place in the Vycor bulb.

In order to prevent collapse of Vycor bulbs during treatments at 1000° to 1150°C a reduced pressure of argon was admitted to the bulbs at room temperature. The argon pressure was regulated so that it would balance one atmosphere at the temperature of treatment. The alloys were quenched after heat treating by breaking the Vycor bulb under the surface of cold water to allow direct cooling of the specimens.

One of the first steps in the annealing program was the determination of the optimum treatment to bring the alloys toward equilibrium at the various temperature levels. A program was undertaken to show the effects of increased annealing times, cold work, and repeated cold work-annealing cycles upon the structures of alloys. The results of this program indicated which of the several treatments undertaken appeared to achieve equilibrium conditions for the various alloys. As a factor of safety, cold work prior to the isothermal anneal and substantially longer annealing times than those determined in the above program were employed. The furnace temperature control was within  $\pm 5^\circ\text{C}$  of the reported temperatures.

**Homogenization:** Certain of the high Ti-Cb and Ti-Mo alloys showed coring even after hot forging and annealing treatments. Therefore, it was found

Fig. 3—Extent of the  $\alpha + \beta$  field in iodide titanium-molybdenum alloys.

Fig. 4 (left)—A 2 pct nominal Mo alloy quenched after annealing at 855°C. Isothermally formed  $\alpha$  grains in a matrix of acicular  $\alpha$  transformed from  $\beta$  during the quench. Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X500.

Fig. 5 (right)—A 2 pct nominal Mo alloy quenched after annealing at 746°C. The predominant phase is retained  $\beta$  and the minor phase is isothermally formed  $\alpha$ . Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X500.

necessary to homogenize these alloys at high temperatures to promote sufficient diffusion to eliminate the composition gradients.

As Vycor bulbs were found to be unsatisfactory at temperatures greater than 1150°C, a new method was devised for making these high temperature treatments. The specimens were placed in a hole drilled in a titanium ingot and a titanium cap was welded over the top in the arc furnace under conditions similar to those used for melting alloys. By this method, the specimens were enclosed in a gas-tight container which gettered any oxygen or nitrogen present in the furnace atmosphere. Titanium turnings were placed with the specimens to aid in gettering the small amounts of contaminants present in the inert gas used in the arc melting furnace.

The alloys included in the metallographic studies were homogenized for 20 to 40 hr at 1250°C. The beneficial effect of this treatment in removing coring can be seen by comparing the structures of a 50 pct Mo-Process A titanium alloy with (Fig. 1) and without (Fig. 2) previous homogenization treatments.

In spite of the precautions taken to achieve complete homogenization of the higher Cb and Mo-bearing alloys, it was found that some residual coring still persisted in certain of these. While this is not of great importance in interpretation of microstructures of the alloys whose composition clearly places

them in the single-phase  $\beta$  solid solution field, it would tend to affect the placement of the  $\beta/\alpha + \beta$  boundary, especially at the lower temperature levels, where the rate of diffusion is low. A further discussion of this matter will be given in the sections dealing with Ti-Cb and Ti-Mo systems.

**Solidus Determinations:** A high temperature, vacuum induction furnace similar to the one described by Schramm, Gordon and Kaufmann<sup>5</sup> was constructed for determination of solidus temperatures. A description of this unit, details of operation and temperature calibration are available.<sup>4</sup>

Solidus curves and melting points of the metals were established with the aid of this equipment. The technique employed was to heat an alloy of given composition until visual signs of melting were observed, then quench a series of specimens of the same composition at approximately 20°C intervals below the temperature of observed melting, and examine them metallographically for evidence of incipient melting. The estimated accuracy is discussed along with results of the work in succeeding sections of the paper, under systems to which they apply.

**X-ray Diffraction Method:** X-ray diffraction patterns of iodide titanium alloys which retained the  $\beta$  phase at room temperature were taken with a Debye camera and CuK $\alpha$  radiation. The camera radius was 7.18 cm. The exposure conditions were

Fig. 9 (lower right)—A 9.6 pct Mo alloy quenched after annealing at 797°C.

This alloy is still in the two-phase field, but the  $\beta$  is now retained. Etchant: 1 pct HF, 3 pct  $\text{HNO}_3$  in water. X250.

4 hr at 40 kv and 8 ma, and each line was measured twice. The  $a_s$  values were obtained for each film by extrapolating the plots of  $a$  vs.  $\cos^2\theta$  to  $\cos^2\theta = 0$ .

The alloy specimens were first homogenized for 4 hr at 1400°C and 40 hr at 1250°C. The powders for the X-ray work were then obtained by filing the homogenized samples. The powders were annealed for 1 hr at 860°C in titanium capsules fitted with titanium plugs, and the capsules were sealed in evacuated Vycor bulbs at less than 5 microns pressure. Cooling was effected by quenching the bulbs in cold water. The bulbs were not broken open until

the contents had cooled to room temperature. The powders were then mounted in pyrex capillaries for ease of handling.

### Titanium-Molybdenum System

A limited amount of information exists in the literature on the system Ti-Mo. Kroll<sup>6</sup> has stated that alloys containing up to 5 pct Mo form solid solutions and melt above the melting point of titanium. The Climax Molybdenum Co.,<sup>7</sup> studying Mo-base alloys, found that the solid solubility of titanium in molybdenum is at least 18 to 20 pct. This conclusion was premised upon the identification of second-phase particles as oxides rather than a Ti-Mo intermediate phase. Gonser has stated<sup>8</sup> that, on the basis of powder metallurgical studies,<sup>9</sup> molybdenum has complete solubility in  $\beta$  titanium.

Fig. 10—A 70 pct nominal Mo alloy homogenized at 1250°C.  $\beta$  solid solution. Etchant: 1 pct HF, 3 pct  $\text{HNO}_3$  in water. X250.

The microstructures of alloys with 1.86, 2.36, 3.82, and 4.65 pct Mo have been examined by Craighead, Simmons and Eastwood<sup>10</sup> after annealing for 30 min at temperatures of 788°, 843°, 871°, 899°, 927°, and 955°C, followed by quenching. According to these data, the maximum solid solubility of molybdenum in  $\alpha$  titanium is less than 1.86 pct within the temperature range studied, and the minimum molybdenum solubility in  $\beta$  titanium is between 3.82 and 4.65 pct at 843°C.

**Results:** The analyses of iodide titanium-molybdenum alloys used in determining the phase diagram are listed in Table II. Although Process A Ti-base alloys were first used to establish the approximate phase boundaries of the system, only the more accurate diagram determined with iodide titanium-base alloys is detailed here.

The  $\alpha + \beta$  field is outlined in Fig. 3. The maximum solubility of molybdenum in  $\alpha$  titanium is about 0.8 pct, and the minimum solubility in  $\beta$  titanium, approximately 28 pct at 600°C. The pretreatment and annealing data for Fig. 3 are summarized in Table III. Figs. 4 and 5 show a 2 pct nominal Mo alloy as treated according to the schedule of Table III and quenched from the temperatures 855° and 746°C, respectively. The decrease in amount of  $\beta$  phase with decreasing temperature

may be noted. The change in grain size with annealing temperature is also obvious in these figures.

Figs. 6 to 9 are a series of micrographs of alloys containing 0.75, 3.4, 8.4, and 9.6 pct Mo as quenched from approximately 800°C after the treatments scheduled in Table III. This series shows the structures obtained in the traverse across the  $\alpha + \beta$  field. It may be noted that, at this quenching temperature, the  $\beta$  phase has transformed in the 8.4 pct Mo alloy, but is retained in the 9.6 pct alloy.

The  $\beta/\alpha + \beta$  boundary was difficult to establish at the lower temperatures (650° and 600°C), in part due to a slight residual coring despite homogenizing treatments, and partly due to a slow approach to equilibrium during isothermal annealing in this temperature range. The lower end of this curve is therefore shown as a broken line.

The apparent absence of intermediate phases in this system is indicated by the typical structure of a homogenized 70 pct Mo alloy, Fig. 10, which shows a single-phase,  $\beta$  solid solution. The evidence obtained does not entirely exclude the possibility of the existence of a transformation in the Mo-rich alloys at the lower temperature levels. No system-

Fig. 11—Iodide titanium-molybdenum phase diagram.

atic search was made in this composition-temperature area.

The overall diagram, including the solidus line, is shown in Fig. 11. The accuracy of this solidus curve is, in general, about  $\pm 25^\circ\text{C}$ . This is determined principally by the quenching increments chosen, which were larger than the precision of temperature measurement in this temperature range. The liquidus curve was drawn in to complete the appearance of the diagram and is not based on experimental data.

**Lattice Parameter Measurements of  $\beta$  Phase of Iodide Titanium-Molybdenum Alloys:** Lattice parameter measurements were made on alloys containing 20, 30, 50, 60, 70, 80, and 90 nominal pct Mo by weight. Body-centered cubic  $\beta$  titanium is isomorphous with molybdenum, and  $\beta$  solid solution may be retained by quenching alloys containing as little as 10 pct Mo from 860°C. All of the alloys used for this work were treated in this manner and revealed single-phase structures microscopically.

The data are plotted vs. composition (atomic percent) in Fig. 12. The molybdenum lattice parameter was taken from Barrett.<sup>11</sup> The lattice para-

Fig. 12—Lattice parameter-composition curve for Ti-Mo alloys.

Fig. 13—Comparison of the extent of the  $\alpha+\beta$  fields in the Process A and iodide titanium-molybdenum systems.

meter-composition curves for the Ti-Mo and Ti-Cb systems are based on nominal compositions and therefore can be considered only as qualitative information corroborating the extent of the  $\beta$  solid solution range, rather than quantitative data.

Additions of iodide titanium increase the lattice parameter of molybdenum, but not as a linear function of composition. The parameter curve shows an appreciable negative deviation from Vegard's law.

The Climax Molybdenum Co.<sup>7</sup> has studied the effect of "commercially pure" titanium sponge additions up to about 16 pct (weight) on the lattice parameter of molybdenum. Although the Climax work cannot be compared very readily with the present findings because of the differences in titanium used, type of X-ray specimen, and treatment of specimens, the trend of the parameter curve (indicating strong deviation from Vegard's law) is in general agreement with that of the present data.

The 60, 70, 80, and 90 wt pct Mo alloys displayed diffraction patterns containing low angle lines foreign to the body-centered cubic structures. Solid specimens, treated in a manner identical to that for the X-ray powders, failed to reveal a new phase microscopically. The source of these extra lines was not discovered.

Fig. 16—Iodide titanium-columbium phase diagram.

**Comparison of the Ti-Mo Diagrams:** A comparison between the solid state phase diagrams of iodide titanium-molybdenum and Process A Ti-Mo alloys is depicted in Fig. 13. The  $\beta/\alpha + \beta$  curve for Process A alloys was not extended to 100 pct Ti because it is well known that the transformation of Mg-reduced titanium occurs over a range of temperature. The entire  $\alpha + \beta$  field is broadened by the use of Process A metal rather than iodide titanium. This was expected to be the case in view of the known effect of oxygen and nitrogen in raising the transformation temperature and stabilizing the  $\alpha$  phase.<sup>12</sup> The difference is illustrated by Figs. 14 and 15. Fig. 14 shows a 15.1 pct Mo alloy (iodide base) heat treated at 746°C. The structure consists entirely of  $\beta$  solid solution. Fig. 15 is a 15.6 pct Mo alloy (Process A base) quenched from the same temperature after long annealing. This alloy still contains a considerable amount of  $\alpha$  phase.

The solidus curves determined for the two types of alloys superimpose upon one another within the limits of accuracy of the method; therefore no overall diagram comparison of Process A vs. iodide alloys is presented.

### Titanium-Columbium System

No prior investigation of the phase diagram of this system has been reported. However, Gonser<sup>8</sup> has

Fig. 14 (left)—A 15.1 pct Mo (iodide titanium) alloy quenched after annealing at 746°C. Single phase  $\beta$  solid solution. Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X250.

Fig. 15 (right)—A 15.6 pct Mo (Process A titanium) alloy quenched after annealing at 746°C. Two-phase structure:  $\alpha$  platelets in retained  $\beta$  matrix. Comparing this with Fig. 14 shows that the  $\beta/\alpha + \beta$  boundary extends to higher molybdenum content for Process A titanium-base alloys than for iodide titanium-base alloys. Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X250.

reported that columbium and  $\beta$  titanium form a continuous series of solid solutions. This conclusion is based on results of powder metallurgical studies.<sup>9</sup>

**Results:** The phase boundaries of the  $\alpha$  and  $\beta$  solid solutions were determined by micrographic analysis of iodide titanium-base alloys covering the range 0 to 50 pct Cb in approximately 1 pct steps. Alloys with 40, 50, 60, 70, 80, and 90 pct Cb were used for X-ray diffraction measurement of the  $\beta$  phase lattice parameters, and microscopic examination of samples in a limited number of heat-treated states. Nominal compositions have been used for plotting the results of microscopic observations, because no reliable analytical methods were available for the determination of columbium in titanium alloys. As all iodide-titanium alloy ingots were weighed carefully immediately after melting, and the weight losses were negligible, the nominal compositions were believed acceptable.

Fig. 16 shows the phase diagram of the whole system, and Fig. 17 is an enlarged view of the  $\alpha + \beta$  field. Annealing temperatures lower than 600°C were not used, since it appears that equilibrium would be almost impossible to achieve, even after long-time annealing at these temperature levels. The

Fig. 17—Extent of the  $\alpha + \beta$  field in the iodide titanium-columbium system.

alloys were annealed at eight temperature levels between 600° and 850°C. Table IV gives the pretreatment and annealing data.

As the micrographs shown in the section on the Ti-Mo system are considered representative of both diagrams, duplicate structures are not presented in this section.

The solubility of columbium in  $\alpha$  titanium was found to increase with lowered temperatures to about 4 pct Cb at 600°C. The  $\beta/\alpha + \beta$  boundary could be determined with certainty above 750°C.

Table IV. Schedule of Treatments for Iodide Titanium-Columbium Alloys

|                           | P30-45; XR75; H    |                    | 47-50, 60      |

\* P—Cold compressed, pct. XR—Cold rolled after compression, pct. H—Homogenized, 1250° or 1400°C. W—Cold rolled, pct.

Fig. 18—A 48 pct nominal Cb alloy homogenized, cold pressed, and quenched after annealing at 600°C. Very fine distribution of  $\alpha$  precipitate in retained  $\beta$ . Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X250.

The phase boundary at 700°C, however, could not be located accurately, because of the presence of some residual coring due to lack of complete homogeneity. For example, alloys containing 29 to 34 pct Cb, even after homogenization for 40 hr at 1250°C, cold working, subsequent annealing at 700°C, and quenching, showed very small amounts of  $\alpha$  phase (estimated to be within 1 to 3 pct) in a matrix of transformed  $\beta$ . The transformation of  $\beta$  to acicular  $\alpha$  occurred in all alloys containing less than 36 pct Cb. With higher columbium contents, the  $\beta$  phase was retained on quenching.

The alloys quenched from 650° and 600°C were also subjected to homogenization for 40 hr at 1250°C prior to the final long-time anneal. Even so, all alloys selected for bracketing the phase boundary at 650°C (36 to 44 pct Cb) and 600°C (47 to 60 pct Cb) contained small amounts of the  $\alpha$  phase, varying somewhat irregularly in amount with composition, see Fig. 18. For this reason, the  $\beta/\alpha + \beta$  boundary of Fig. 17 is dotted for temperatures at and below 700°C. This extrapolation of the solid curve is believed to represent conditions close to equilibrium.

In order to determine the constitution of the Cb-rich alloys, specimens with 50, 60, 70, 80, and 90 pct Cb were homogenization-annealed for 4 hr at 1400°C and 40 hr at 1250°C. Fig. 10 is representative of the structures of these alloys, indicating that the  $\beta$  field extends over the entire composition range at high temperatures.

As a further check, the lattice parameters of the  $\beta$  phase between 40 and 90 pct Cb (25.8 and 83.1 atomic pct) were determined. The data are plotted in Fig. 19. Additions of iodide titanium decrease the lattice parameter of columbium. This change follows a small negative deviation from Vegard's law.

As was the case with Ti-Mo alloys, the diffraction

Fig. 19—Lattice parameter-composition curve for Ti-Cb alloys.

Fig. 20—A 90 pct nominal Cb alloy homogenized then heated to a temperature above the solidus curve, 2245°C, and quenched. The "bubbles" in the structure are typical signs of incipient melting. Etchant: 1 pct HF, 3 pct HNO<sub>3</sub> in water. X250.

patterns of alloys with 70, 80, and 90 pct Cb contained lines foreign to the body-centered cubic solid solution in low angle regions of the film, which were not successfully identified. Solid specimens, heat treated in the same manner as the X-ray powders, did not reveal microscopic evidence of a transformation in this composition range. This single treatment, however, does not completely rule out the possibility of a low temperature transformation in this system.

The solidus curve shown in Fig. 16 was determined with homogenized alloys. The microscopic evidence of incipient melting for all of these alloys is exemplified by Fig. 20, showing a 90 pct Cb alloy quenched from above the solidus temperature. The overall accuracy of this curve is limited by the temperature increments employed in the incipient fusion method. For this diagram, the accuracy may be taken as  $\pm 25^\circ\text{C}$ .

The solidus temperature increases continuously with increasing columbium content. The melting point of iodide titanium was found to be  $1720^\circ\text{C}$ , as compared with  $1727^\circ\text{C}$  given by deBoer.<sup>13</sup> The melting point of columbium is reported as  $2415 \pm 15^\circ\text{C}$ ;<sup>14</sup> it was determined experimentally to be  $2410^\circ\text{C}$ . The dotted liquidus curve in Fig. 16 was not determined experimentally but was included to complete the appearance of the diagram.

The features of the Process A titanium-columbium phase diagram are similar to those of the iodide titanium-columbium phase diagram. The difference appears to be that the  $\alpha + \beta$  field in the Process A titanium alloys is somewhat wider than that in the iodide titanium alloys. This same relationship was found for the Ti-Mo alloys described in the previous section.

### Summary

**Titanium-Molybdenum:** Ti-Mo phase diagrams were determined with both DuPont Process A and iodide titanium-base alloys. Both diagrams have the following features:  $\beta$  titanium and molybdenum form a continuous series of solid solutions. A constantly rising solidus curve connects the melting points of titanium and molybdenum. The  $\alpha$  to  $\beta$  transformation temperature of titanium ( $885^\circ\text{C}$ ) is lowered by the addition of molybdenum, with a broadening of the  $\alpha + \beta$  field with decreasing temperature.

The solubility of molybdenum in  $\alpha$  titanium is less than 0.8 pct Mo at temperatures between  $885^\circ$  and

$600^\circ\text{C}$  for both Process A and iodide titanium-base alloys. The  $\beta/\alpha + \beta$  boundary is essentially a straight line in both phase diagrams. For iodide-base alloys, it extends from the transformation temperature of titanium to about 24 pct Mo at  $650^\circ\text{C}$ . Impurities in Process A titanium shift the  $\beta/\alpha + \beta$  boundary at  $650^\circ\text{C}$  to about 26 pct Mo. X-ray diffraction results show that molybdenum additions decrease the lattice parameter of  $\beta$  titanium in accordance with a negative deviation from Vegard's law.

**Titanium-Columbium:** The Ti-Cb phase diagram determined with iodide titanium-base alloys has the following features:  $\beta$  titanium and columbium form a continuous series of solid solutions, and the solidus curve constantly rises from the melting point of titanium to that of columbium. Columbium lowers the  $\alpha$  to  $\beta$  transformation temperature of titanium, with the resulting  $\alpha + \beta$  field broadening with decreasing temperature. The solubility of columbium in  $\alpha$  titanium increases with fall in temperature to about 3 pct Cb at  $600^\circ\text{C}$ . The  $\beta/\alpha + \beta$  boundary for  $850^\circ$ ,  $800^\circ$ , and  $750^\circ\text{C}$  lies at 3.5, 10.5, and 20 pct Cb, respectively. Because some residual coring remained in the heat treated alloys with more than 25 pct Cb, even after homogenization annealing treatments, this curve could not be determined with high accuracy for temperatures of  $700^\circ\text{C}$  and lower. However, there is certain evidence to indicate that it lies close to 30 pct Cb at  $700^\circ\text{C}$ , and between 50 and 55 pct Cb at  $600^\circ\text{C}$ . X-ray diffraction results show that columbium additions increase the lattice parameter of  $\beta$  titanium in accordance with a small negative deviation from Vegard's law.

### Acknowledgments

The authors are grateful to the Materials Laboratory, Engineering Division, Air Materiel Command, who sponsored this work, for permission to publish this paper. Acknowledgment is also made of the many associates of the Armour Research Foundation who contributed to the results. Particular recognition is given to R. J. Van Thyne, who prepared many of the alloys, and C. A. Johnson, who was responsible for the metallographic work.

# On the Mechanism and Kinetics of the Scaling of Iron

by M. H. Davies, M. T. Simnad, and C. E. Birchenall

The transport mechanisms previously proposed in wüstite and hematite have been confirmed by movement of inert markers during the growth of these phases. By similar measurements the mechanism for magnetite has been determined. The rates of growth of multilayer scales on iron, magnetite and hematite on wüstite, and hematite on magnetite have been measured. All rates are found to be diffusion controlled under the conditions of the experiments.

MANY studies have been made of the rate of oxidation of iron in both the low temperature, film-forming region and the high temperature scaling range. The interpretation of the results has been greatly complicated by the formation of multilayered scales containing the various phases of iron oxides. In most cases no attempt has been made to determine the composition of the scale and its dependence on time of oxidation in a quantitative manner. However, several recent studies<sup>1-3</sup> have taken this variable into account.

It is generally agreed that the growth of thick scales on iron follows a parabolic rate law for the increase of total thickness. In the thin film region agreement has been claimed with parabolic equations of various forms and with logarithmic equations. The discussion here will be concerned only with the formation of scales of considerable thickness, greater than several microns, although some of the conclusions may be applicable to thin films.

A brief survey will be given of the solid phases of the iron-oxygen system, the stability of wüstite in bulk and in thin films, the relative densities of iron in the metal and oxides, and the kinetics of forma-

tion of oxide scales on iron. New experimental results will be introduced at several points during the discussion, and an attempt will be made to formulate a mechanistic picture consistent with these observations. The experimental techniques are described in an appendix.

## Iron-Oxygen System

Fig. 1a shows the iron-oxygen phase diagram.

**Wüstite ("FeO"):** The lowest of the oxides has a NaCl type cubic lattice formed by close-packing of the relatively large oxide ions with the smaller iron ions arranged in the interstices. The ionic radius for  $O^{2-}$  is about 1.3 Å, while  $Fe^{2+}$  has a radius of about 0.8 Å and  $Fe^{3+}$  about 0.7 Å. Its range of existence on the phase diagram is very wide for an ionic material of this type and does not seem to include the stoichiometric composition FeO. These deviations appear to be well established as vacancies on iron lattice sites by the comparison of lattice parameters and densities for a series of compositions by Jette and Foote.<sup>4</sup> The limits of the field are disputed, but the work which seems most reliable<sup>5</sup> indicates vacancies in from 5 pct to more than 12 pct of the iron sites. In order for the crystal to be electrically neutral, there must be electron holes which correspond to the formation of trivalent iron ions equal to twice the number of vacancies.

**Magnetite ("Fe<sub>3</sub>O<sub>4</sub>"):** Considerable disagreement also exists in the literature about the stable range of the Fe<sub>3</sub>O<sub>4</sub> field. Some diagrams show the Fe<sub>3</sub>O<sub>4</sub> composition to be lower in oxygen than the formula indicates, but Schenck<sup>6</sup> gives a diagram from the

- f*—Proeutectoid magnetite in matrix of wüstite. X500.

work of Benedicks and Lofquist<sup>7</sup> which indicates an oxygen excess. Darken and Gurry<sup>8</sup> report similar results. More recent studies by Verwey and Haayman<sup>9</sup> based upon X-ray parameter studies and the measurement of electronic conductivities support the latter. They believe that  $\text{Fe}_3\text{O}_4$  can increase its oxygen content by forming regions closely resembling  $\gamma\text{Fe}_2\text{O}_3$  which has a structure similar to  $\text{Fe}_3\text{O}_4$ . Both of these oxides are cubic with their structures largely determined by the close-packing of oxide ions, so the correspondence is not surprising.

**Hematite ("Fe<sub>2</sub>O<sub>3</sub>"):** The hematite ( $\alpha\text{Fe}_2\text{O}_3$ ) field probably is slightly oxide ion deficient, since the divalent and trivalent states of oxidation are the only ones readily available to iron. This is confirmed by the conductivity studies of Bevan, Shelton, and Anderson,<sup>9</sup> who conclude that the deficiency leads to oxide site vacancies or interstitial iron ions. Ionic transport in this phase is probably by oxide ions as compared with wüstite where iron is almost certainly the mobile constituent. Pryor and Evans<sup>10</sup> make use of this in explaining the dissolution behavior of hematite in acids. Preliminary diffusion measurements for iron in hematite by Himmel<sup>11</sup> indicate a negligible diffusion rate for iron ions, favoring transport by oxide vacancies rather than interstitial iron ions.

In addition to  $\alpha\text{Fe}_2\text{O}_3$ , a cubic form,  $\gamma\text{Fe}_2\text{O}_3$ , may be prepared by dehydration of  $\gamma\text{FeOOH}$  below 500°C or by oxidation of  $\text{Fe}_3\text{O}_4$  up to 400°C. When  $\gamma\text{FeOOH}$  is dehydrated above 500°C,  $\alpha\text{Fe}_2\text{O}_3$  forms. If the dehydration product formed below 500°C is held above 350°C, it will eventually transform to  $\alpha\text{Fe}_2\text{O}_3$ . Above 400°C  $\text{Fe}_3\text{O}_4$  oxidizes to  $\alpha\text{Fe}_2\text{O}_3$ . Although transformation temperatures are given in the range of 150° to 400°C, no evidence could be found in the literature for the transformation of  $\alpha\text{Fe}_2\text{O}_3$  to  $\gamma\text{Fe}_2\text{O}_3$  at any temperature. In fact, Fricke and his co-workers<sup>12</sup> have measured heats of solution of both forms in acid at 20° to 32°C and found that  $\gamma\text{Fe}_2\text{O}_3$  has a heat content in excess of that of  $\alpha\text{Fe}_2\text{O}_3$  of more than 6 kcal per mol for crystals of the same particle size. It appears that  $\gamma\text{Fe}_2\text{O}_3$  is a metastable growth form which is the product of dehydration of  $\gamma\text{FeOOH}$  and of the oxidation of  $\text{Fe}_3\text{O}_4$  because of its resemblance in structure to the reactants.

$\alpha\text{Fe}_2\text{O}_3$ , the only form to be considered here, is a rhombohedral crystal<sup>13</sup> (the  $\alpha$  corundum structure) with the oxide ions in nearly close-packed hexagonal arrangement. The iron ions reside in the interstices.

#### Eutectoid Decomposition of Wüstite

Chaudron and Forestier<sup>14</sup> studied this reaction on bulk "FeO" and found that the process behaved as

a normal nucleation and growth process with a maximum rate at about 470°C, as shown in Fig. 2. They also found the iron metal precipitated at the oxide grain boundaries.

Although the normal transformation temperature is about 570°C, Gulbransen and Hickman<sup>15</sup> have shown that in thin films upon Fe, "FeO" exists at temperatures as low as 400°C. This lower limit of existence is strongly dependent upon film thickness and shifts toward 570°C as the film becomes thicker. When the transformation occurs on cooling, little iron is found in the oxide, so it is possible that, when the film is thin and an iron substrate is present, the iron may diffuse back to the interface and plate out on the substrate.

More recently Gulbransen and Ruka<sup>16</sup> have carried out an electron diffraction investigation of this reaction, the reverse reaction, and also reactions involving  $\alpha\text{Fe}_2\text{O}_3$  in films on metal surfaces. They confirmed the above results and eliminated former discrepancies between phases reported in scales by electron diffraction methods as compared with X-ray and micrographic techniques.

### Relations Between Phases

Bozorth,<sup>17</sup> Pfeil,<sup>18</sup> Heindlhofer and Larsen,<sup>19</sup> and Fischbeck and Salzer<sup>20</sup> have demonstrated that in strongly oxidizing atmospheres and at temperatures somewhat above 570°C the oxides of iron form in successive layers on the metal in accordance with the principle of LeChatelier, the lowest valence oxide next to the metal, the highest in contact with the atmosphere. At room temperature the densities of iron ions in the metal and oxides in the above

order are:  $7.85 \frac{\text{g Fe}}{\text{cc Fe}}$ ,  $4.43 \frac{\text{g Fe}}{\text{cc FeO}}$ ,  $3.74 \frac{\text{g Fe}}{\text{cc Fe}_3\text{O}_4}$ ,  $3.67 \frac{\text{g Fe}}{\text{cc Fe}_2\text{O}_3}$ . It is evident that the system fulfills

the density ratio conditions of Pilling and Bedworth<sup>21</sup> for the formation of continuous layers.

At the interfaces between successive layers definite orientation relationships have been observed. McCandless and Mehl<sup>22</sup> have studied wüstite formed on Fe and found that there is a (001) plane of iron atoms common to both phases, with the 010 direction of wüstite parallel to the 110 direction of Fe. The same investigators concluded that wüstite and magnetite had a common (001) plane of oxide ions. Similarly, between magnetite and hematite Gruner<sup>23</sup> showed the matching in an oxide ion plane of the basal (0001) plane of  $\alpha\text{Fe}_2\text{O}_3$  with the (111) plane of  $\text{Fe}_3\text{O}_4$ . The disorder of iron ion in crossing this last interface is quite large, but in the  $\text{FeO-Fe}_3\text{O}_4$  case the iron positions on either side of the common plane are partially in fair agreement.

No specific study of the relationship between  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{Fe}_2\text{O}_3$  seems to have been made, but the two give practically indistinguishable electron diffraction patterns, so that a match on the cubic oxide ion planes seems likely. More important is the relationship between  $\gamma\text{Fe}$  and wüstite which has not been determined. That coherency exists is indicated from the fact that protective scales form. Only a common iron plane is possible. The results of Fischbeck and Salzer<sup>20</sup> may indicate the fit is sufficiently poor to constitute an appreciable resistance, but nothing in the new work reported here confirms this.

Goldschmidt<sup>24</sup> has examined the relative volumes and structures of the metal and the cubic oxides and

Fig. 2—Decomposition of wüstite (after Chaudron and Forestier) showing percentage of "FeO" decomposed or recombined in 24 hr.

obtained numerical comparisons which illustrate the smallness of the adjustments which must be made to fit the lattices together at an interface.

### Transport Mechanisms

The transport mechanisms in oxides may be studied in at least three different ways.

1—The electrical conductivity<sup>25</sup> may be studied at several temperatures as a function of the partial pressure of oxygen in equilibrium with the specimen.

2—Self-diffusion coefficients<sup>26</sup> of both ions may be determined in the oxide.

3—"Kirkendall effects," the movement of inert markers in the diffusing systems, may be measured as first attempted by Pfeil<sup>18</sup> in 1929. Pfeil used slurries of  $\text{NiO}$  or  $\text{Cr}_2\text{O}_3$  painted on the metal surfaces as inert markers. After oxidizing the surface, he sought the position of the markers in the oxide. The results were not conclusive. The markers were found in the wüstite layer, but the layer was mechanically separated into two parts at the point where the impurities were concentrated. The location of the markers appears to have been determined partly by the mechanical separation of scale from metal during oxidation.

New measurements of this last type have been made using radioactive silver as inert markers. This has many advantages for this particular application since it neither dissolves in the metal and its oxides, nor oxidizes at these temperatures. Furthermore, very small amounts can be detected on a polished cross-section by autoradiographic methods, so that very thin deposits of silver may be used. These were applied by wetting a silk thread in active silver nitrate solution and touching each side of the iron or iron oxide plates twice or more, leaving parallel wet marks. These were dried and the silver nitrate decomposed to silver in the preliminary heating of the sample before oxidation began.

Three series of these studies were carried out: 1—iron metal was marked, then scaled in oxygen to give a multilayer scale; 2—wüstite was marked, then reacted completely to magnetite in water vapor;

Fig. 3a—Isothermal curves for the rate of increase of weight of iron oxidized in oxygen.

Fig. 3b—Isothermal curves for the rate of increase of weight of iron oxidized in oxygen.

3—magnetite was marked, then partially reacted to hematite in oxygen. In case 1 the markers were found precisely at the metal-oxide interface. In case 2 the markers were found almost at the outside surface. In case 3 the markers could not be found. It was concluded that the silver remained on the outer surface, from which it vaporized during the long oxidation treatment required to form an appreciably thick layer of the slowly growing hematite.

From these measurements the following conclusions may be drawn about the transport mechanisms leading to the growth of the oxides of iron:

1—Wüstite grows almost entirely by diffusion of iron ions. Oxide ions are added at the outer face of the phase and remain essentially fixed.

2—Magnetite grows largely by oxide ion diffusion (which may indicate a need for review of the deviations of the phase field from the stoichiometric  $\text{Fe}_3\text{O}_4$  composition), but there seems to be an appreciable contribution from iron ion diffusion—about 20 pct.

3—Hematite grows by oxide ion diffusion with practically no iron ion participation. Iron ions are added at the inner face and stay fixed.

These findings are in accord with the information available on wüstite and hematite, the former cation conducting, the latter anion conducting. The new result on magnetite is rather surprising, but not in conflict with any previous work known to the

authors. This is being checked by method 2 in this laboratory.

#### Kinetics of Oxidation

In the many studies of the oxidation of iron to form multilayered scales, fairly good agreement for the rate constants over most of the temperature range investigated has been obtained. However, at the higher temperatures discontinuities have been reported in the plot of the variation of the logarithm of  $k$ , the parabolic rate constant, against the reciprocal of the absolute temperature. This discontinuity has been attributed both to the effect of the magnetic transformation in iron at  $760^\circ\text{C}$  and also to the  $\alpha$  to  $\gamma$  phase transformation at  $910^\circ\text{C}$ .<sup>1,20</sup> In the endeavor to resolve this controversy and also to check the work of Benard and Coquelle<sup>1</sup> on the kinetics of growth of the individual phases in the scale, it was decided to investigate the oxidation of iron over the temperature range  $400^\circ$  to  $1200^\circ\text{C}$  under very precisely controlled conditions.

A full account of the experimental methods and techniques is given in the appendix, but it is well to point out the essential differences here. With the exception of Gulbransen and others in work on the kinetics of formation of thin films, 1—oxidation studies have generally employed air, subject to variation in composition and humidity as the oxidizing medium; 2—oxidation has been allowed to proceed

| 1090                          | 25        | 94         | 5                             | <1                            | 49        | 94         | 5                             | <1                            |           |            |                               |                               |

during the initial heating period before the specimen reaches the temperature of the furnace. In the present series of experiments pure dry oxygen was used and in addition the time and surface for the beginning of oxidation were precisely defined. This was accomplished by first heating the specimen in hydrogen at 700°C or above to reduce any air-formed film, and then allowing the specimen to attain equilibrium in a highly purified argon atmosphere in the furnace before introducing oxygen. Under these conditions the rate of growth of the total scale was obtained by measuring the increase of weight of the specimen during certain fixed times of oxidation, and the results are shown in Fig. 3. From these results, values for the parabolic rate constant,  $k$ , were obtained for the particular temperatures and the standard plot of  $\log k$  vs. the reciprocal of the absolute temperature is given in Fig. 4.  $k$  is defined by the Pilling and Bedworth equation  $(W/A) = kt^{1/2}$ , where  $W$  is weight gain,  $A$  is area, and  $t$  is time.

Specimens were mounted and sectioned, and the thicknesses of the individual phases were obtained microscopically. The results indicated that in no case, above a temperature of about 625°C, did the scale contain greater than 10 pct by volume of the higher oxides  $Fe_3O_4$  and  $Fe_2O_3$ . Values for the relative thicknesses of the oxides for various times at different temperatures are given in Table I. However, the measurement of the thickness of the two higher oxides could not be made with great precision and more sensitive techniques were devised for the measurement of their growth rates. Values for the increase in thickness of "FeO" are plotted in Fig. 5, and the parabolic rate constant for the growth of this phase approximates that for the growth of the total scale at temperatures above 625°C.

To measure the rate of growth of  $Fe_3O_4$  and  $Fe_2O_3$ , samples of "FeO" and  $Fe_3O_4$  were prepared and these were oxidized in oxygen using a spring balance to determine continuously the rate of increase of weight with time. The results obtained are shown in Figs. 6 and 7, and the rate constants obtained from these results for the oxidation of "FeO" to  $Fe_3O_4$  and  $Fe_3O_4$  to  $Fe_2O_3$  are plotted on Fig. 4.

The main differences between the results obtained in this investigation and previous studies may be summarized as follows:

1—The parabolic rate constant  $k$  in the temperature range 400° to 600°C is lower than that obtained by Stanley and coworkers.<sup>3</sup> It is believed<sup>27</sup> that the discrepancy existing between the true surface area and that calculated from the geometrical dimensions of the specimen led to the higher values for  $k$  calculated by these workers, particularly for the relatively short oxidation times that they employed. In the present investigation the actual surface areas more nearly approach the calculated surface area due to (a) the more highly polished nature of the specimen, and (b) the pre-oxidation anneal in hydrogen at 700°C. The longer oxidation times employed also yield values of  $k$  which more nearly approximate the true value.

2—The inflection in the plot of  $\ln k$  vs.  $1/T$  at about 600°C is associated with the appearance of "FeO" as a stable component of the scale.

3—In the temperature range 600° to 1200°C the variation of  $\ln k$  with  $1/T$  is expressed by a smooth curve, the slope of which changes rapidly at about 800°C, coinciding with the appearance of a finite thickness of  $Fe_2O_3$  in the scale. That is,  $\ln k$  is not a simple linear function of the reciprocal of the

Fig. 4—Plots of the logarithm of the parabolic rate constants for the oxidation of iron, wustite, and magnetite in 1 atm of oxygen vs. the reciprocal of absolute temperature.

absolute temperature, and the so-called inflection previously obtained is not attributable to the phase<sup>3</sup> or magnetic transformation in pure iron. This point will be elaborated later.

4—Microscopic measurements indicate: (a) that at no temperature above about 625°C do the higher oxides,  $Fe_3O_4$  and  $Fe_2O_3$ , form a considerable portion of the scale, (b) the growth of these higher oxides is not linear with time. These results are in direct contradiction to the work of Benard and Coquelle.<sup>1</sup> It is believed that, since the technique employed in the experiments of Benard and Coquelle involves heating the specimen from room temperature to the oxidizing temperature in the oxidizing atmosphere, a thick film is formed during this initial heating period. At the transformation temperature where the metal suffers a contraction, the film may become partially divorced from the metal. If the film is plastic at 910°C, then no rupture will occur and the effect of the partial divorcement of scale and

Fig. 5—Rate of growth of "FeO" from microscopic measurement.

Fig. 6—Parabolic plot for the oxidation of "FeO" in oxygen.

metal will be to reduce the area of contact, thus reducing the supply of iron ions to the scale. This will manifest itself both as a reduction in the total overall rate of oxidation and in the increase in the percentage of the higher oxides in the scale. That is, the percentages of  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$  will be greater than in a system which is in dynamic equilibrium when the contact between phases is perfect.

Some supporting evidence for the results of the present investigation have been obtained: (a) in the oxidation of iron in water vapor, the overall rate approximates the total oxidation rate in oxygen, but the percentage of  $\text{Fe}_3\text{O}_4$  in the scale remains small until all the iron has been converted to oxide; (b) stress concentration effects at corners and edges of specimens can result in the local separation of scale and metal at some period during oxidation. When this occurs, its effect is to increase locally the amount of the higher oxides in the scale.

5—Results for the rate of oxidation of wüstite and magnetite, Figs. 6 and 7, give a parabolic relationship between gain in weight and time. This shows that the processes are diffusion controlled since an interface reaction controlled process would manifest itself in a linear rate law. The rates of growth derived for the higher oxides under these

conditions will be greater than their respective growth rates during the formation of scale, but it will be shown that they do not affect materially the total oxidation rate above 600°C.

### Analysis of the Kinetic Data

Considering oxidation in the range 400° to 570°C in the absence of changing composition limits for the phases  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$  with temperature, the plot of  $\ln k$  vs.  $1/T$  will yield a straight line. This results from the fact that the growth rate will be a simple function of the average diffusion coefficient for the components of the scale.

The rate of growth of  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$  on iron, i.e., below 570°C, is largely dependent upon diffusion in  $\text{Fe}_3\text{O}_4$  since this forms nearly 100 pct of the scale.<sup>1-3</sup> This rate should bear some relationship to the rate of growth of  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$  on "FeO" where magnetite is again the major component.

The reactions involved, neglecting the formation of  $\text{Fe}_2\text{O}_3$ , are:

On the basis of formation of the same thickness of

Fig. 7—Curves for the increase of weight with time of magnetite oxidized in oxygen. Approximate values for rate constants are derived from the straight portions of the plot of  $W/A$  vs.  $\text{time}^{1/2}$ .

$\text{Fe}_3\text{O}_4$ , it can be seen that the weight gain in process 1 is four times the weight gain in process 2. Examination of Fig. 4 shows that the extrapolated values for process 1 are four to five times greater than those measured for process 2 at the same temperature. The activation energies are nearly the same.

Above 570°C the picture becomes more complex owing to the wide variation of the composition limits of the "FeO" phase field with temperature. The oxidation process is dependent on diffusion and, in turn, the diffusion rate varies with the concentration gradient in the growing phase. In a phase field with fixed composition limits whose difference is  $\Delta C$ , the only factor affecting diffusion is the actual thickness of the phase,  $\Delta X$ , with respect to those fixed composition limits, and the effect of a changing

$\frac{\Delta C}{\Delta X}$  due to a change in  $\Delta X$  is implied in the normal

parabolic law. When  $\Delta C$  changes also (as in "FeO"), there is another contribution to the rate of diffusion and hence to the rate of growth of the phase. Thus  $\ln k$  will not be a simple function of the reciprocal of the absolute temperature, and the curvature of this relationship is attributed to a changing  $\Delta C$  with temperature in "FeO." That is, for the same thick-

ness of "FeO" formed at different temperatures, there will be an effect on the growth rate due to the fact that the composition limits of the phase will be different, in addition to the normal increase of  $D$ , the average diffusion coefficient, with increase in temperature. Booth<sup>28</sup> has shown that the variation of the diffusion coefficient with concentration does not vitiate the application of the parabolic rate law at any one temperature.

In the absence of interface reaction rate control in the oxidation process, there appears to be no basis for the assumption that phase transformations in the metal can affect the rate of growth. Experiments on the oxidation of manganese<sup>30</sup> show no effect on the parabolic rate constant due to the  $\alpha$  to  $\gamma$  transformation in that metal. However, this does not imply that such effects will not be present under conditions of nonparabolic oxidation.

### Summary

The rates of oxidation of iron in pure oxygen have been determined with good precision over a wide range of temperatures. In general, the overall rates agree with those previously reported, but several systematic differences are noted. Tentative explanations are offered for these differences.

In addition to multilayer scaling rates, the rates of growth of hematite on magnetite and hematite and magnetite on wüstite have been determined. In contradiction with the results of Benard and Coquelle, obtained by micrographic measurements, these rates have been observed to follow a parabolic law rather than a linear law. On the basis of these measurements, it was concluded that the growth of each layer is a diffusion controlled process and that the interface reaction rates may be neglected. The process thus fulfills adequately the assumptions necessary to apply the Valensi<sup>30</sup> treatment of multilayer scaling.

Observing the Kirkendall effects in the growth of each of the oxide phases, with a modification of the Pfeil technique using radioactive silver as inert marker, established the diffusing component for each phase. The process is illustrated schematically in Fig. 8, where the percentages in magnetite are rough values applying at one temperature only.

Below 570°C the overall rate is determined by the growth rate of  $\text{Fe}_3\text{O}_4$ . Above about 620°C, the overall rate seems to be determined principally by the rate of FeO growth. Between 570° and 620°C, as the temperature increases the rate controlling layer changes from  $\text{Fe}_3\text{O}_4$  to FeO, leading to a marked curvature in the  $\log k - 1/T$  plot.

The parabolic rate constant is a complex function of temperature in the growth of layers such as "FeO" where the range of existence of the phase, as well as the diffusion coefficients, for a given composition depends strongly upon temperature.

The rates of growth of iron oxide layers are rather insensitive to changes in the substrate. There seems to be no great change in the rate of growth of FeO when the substrate changes from  $\alpha$  to  $\gamma$  Fe, and no great change in the rate of growth of  $\text{Fe}_3\text{O}_4$  when the substrate changes from  $\alpha$ Fe to FeO.

### Appendix

#### Experimental Methods and Techniques

**Apparatus:** In these experiments three vertical furnaces were equipped with a glass manifold, constructed so that each furnace could be independently connected to a source of hydrogen, oxygen or argon, or to a vacuum pump.

The design of one of the furnace units is shown, Fig. 9, including the glass winch which served to raise and lower specimens to and from a predetermined position in the furnace.

Each specimen was attached to a silica rod by a platinum hook and the silica rod was in turn attached to the winch by means of nylon thread. Spokes attached to the bottom end of the silica rod prevented the specimen touching the thermocouple sheathing or the wall of the furnace tubing itself.

For some experiments, particularly those concerned with the oxidation of the lower oxides of iron, it was desirable to follow the course of oxidation continuously. This was accomplished by means of a sensitive spring balance. The glass head, containing the winch, of one of the furnaces was extended considerably so that both ends of the spring (which were attached to the winch and to the silica by nylon thread) could be observed with a cathetometer to measure the length of the spring accurately. An alloy of low temperature coefficient of elastic properties, "Nispan C" wire 0.005 in. diam was used for the spring, with a sensitivity of ap-

proximately 0.02 cm per mg. Measurements were reproducible to 0.010 cm, which corresponded to a weight change of 0.5 mg.

Adequate precautions were taken to purify the gases used. The argon was periodically tested by holding a heat-tinted specimen in one of the furnaces in an atmosphere of the gas at 700°C and noting any changes in the appearance of the specimen. The atmosphere was considered satisfactory if no change occurred in the interference color or if a slight reduction in the thickness of the film was indicated.

**Preparation of Specimens and Experimental Procedure:** The iron used in these experiments was Westinghouse Puron. All specimens after cutting and surface grinding were annealed in hydrogen for 24 hr at 900°C. Subsequently, the specimens were hand ground under alcohol on metallographic polishing papers to a fineness of 4/0. They were then washed in alcohol, dried, measured and weighed, rewashed, and then loaded into the furnaces.

The specimens used were approximately  $\frac{3}{4} \times \frac{1}{2} \times 1/10$  in. and their dimensions were accurately measured with a micrometer screw gage so that the total surface area could be computed. A standard chemical balance sufficed for most weighings; however, in those cases where the expected weight increase was relatively small (i.e., for oxidation at low temperatures and for short times), an assay balance was used.

It was believed that the presence of an air-formed film on the surface of the Puron might lead to erroneous results, particularly for the oxidation of specimens at low temperatures and for short times. Consequently, all specimens were given a pre-oxidation anneal in hydrogen at 700°C or above. If the particular oxidation experiment was to be carried out below 700°C, then, following the preliminary hydrogen anneal at 700°C, the specimen was raised to the cool zone, the furnace chamber evacuated, argon admitted, and the furnace allowed to cool to the oxidation temperature desired. Those specimens to be oxidized above 700°C were hydrogen annealed at the oxidation temperature. In all cases, oxygen was not admitted to the furnace until the specimen had reached the equilibrium oxidation temperature in argon. This procedure avoided any spurious effects that might have resulted from oxidation having occurred over a range of temperature in the initial stages.

For the studies on the oxidation of oxides, "FeO" was prepared by oxidizing iron in water vapor. The time of oxidation was calculated so that only a small amount of  $\text{Fe}_3\text{O}_4$  would be produced and this was removed by grinding. "FeO" could also be produced by oxidation of iron in hydrogen-water vapor or carbon monoxide-carbon dioxide mixtures.

The  $\text{Fe}_3\text{O}_4$  was produced by oxidizing iron to constant weight in water vapor.

**Mounting Technique:** Many of the conventional mounting methods were tried; all those involving thermal setting with or without pressure were rejected due to the break up in scale which they frequently occasioned.

The method finally developed and adopted involved making a sandwich of the specimen between two small sheets of polystyrene. A solution of polystyrene in ethylene bromide was used as a cement. After the cement was hardened (in 24 to 36 hr) the protruding ends of the polystyrene were softened and then welded to other pieces of polystyrene to give the mount greater security in the grinding operations. This type of mounting proved adequate for the polishing of the oxides so that thickness measurements might be taken.

**Radioactive Tracer Technique:** The movement of inert markers placed at an interface across which diffusion takes place has been previously studied (Smigelskas and Kirkendall,<sup>31</sup> Da Silva and Mehl<sup>32</sup>). The application of the active silver to the specimen has been described previously. After oxidation, the specimen was mounted, sectioned perpendicular to the flat face, and polished. The polished edge was placed in in-

timate contact with a spectrographic or No-Screen X-ray plate. After a sufficient period of exposure, the plate was developed, and the separation of the streaks due to the active silver on either face of the sample was measured.

### Acknowledgments

This work was supported by the Office of Naval Research. The  $\text{Ag}^{110}$  used herein was obtained from the Isotopes Division, U. S. Atomic Energy Commission. The work was facilitated by a fellowship grant by the Economic Cooperation Administration to one of us. The continuous interest of Robert F. Mehl in this work was greatly appreciated.

# Effects of Tungsten or Molybdenum Upon the Alpha-Beta Transformation and Gamma Precipitation In Cobalt-Chromium Alloys

by E. E. Fletcher and A. R. Elsea

This paper describes a metallographic investigation of the influence of tungsten or molybdenum additions upon the transformation and precipitation reactions occurring in Co-rich Co-Cr alloys. It is shown that tungsten has little effect upon the  $\alpha$ - $\beta$  transformation temperature range, while molybdenum tends to raise it. Both elements tend to promote the formation of  $\gamma$  phase, molybdenum being more potent in this respect than tungsten.

HIGH temperature alloys, that is, alloys which have load-carrying ability at elevated temperatures, have been developed at an increasing rate during the past few years. This has resulted from the requirements in the design of modern aircraft engines. Although many alloys of this type are available, they have been developed on an empirical basis. Metallurgists do not have a clear understanding of the phases or structures that are responsible for these high temperature properties.

In order to determine why these alloys possess this particular ability, a project was started at Battelle Memorial Institute with the object of learning more about the fundamental factors which promote high temperature strength in alloys. This study was to include a correlation of microstructure and the high temperature properties of Vitallium, an alloy which is widely used for high temperature service. Vitallium is a complex material both from the standpoint of composition and microstructure. Consequently, it was necessary to obtain informa-

tion regarding the phase relationships in this alloy.

The Co-Cr binary diagram was determined as the first phase of this investigation.<sup>1</sup> A second paper described the effects of iron, nickel, or nitrogen on the reactions occurring in the Co-rich end of this system.<sup>2</sup> The present paper covers a continuation of this investigation in which the effects of tungsten or molybdenum on the reactions occurring in Co-rich, Co-Cr-base alloys were determined.

## Preparation of Test Materials

Two series of ternary Co-Cr-base alloys, representing Co-Cr ratios of 80:20 and 68:32

$\left( \frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 20 \text{ and } 32 \right)$ , were prepared containing

up to 6 pct W and up to 12 pct Mo.

Melting stock consisted of electrolytic Co, electrolytic Cr, 99.9 pct pure W, and 99.9 pct pure Mo. Table I lists the chemical analyses of these materials.

The melting furnace was a vertical porcelain tube

heated by a tubular Globar element and was designed for controlled-atmosphere melting. A purified argon atmosphere was used in all of the melting operations. High purity tank argon (99.87 or 99.92 pct argon) was passed through magnesium perchlorate to remove the moisture and then through a container of titanium-metal granules heated to 750°C for removal of nitrogen and oxygen.

The 200-g charges were melted in Alundum thimble crucibles which absorbed chromium oxide and tended to deoxidize the melts. Close-fitting graphite sleeves were used to support the crucibles during charging, melting, and casting. The alloys picked up about 0.1 pct C during melting. However, during subsequent homogenization, the carbon was usually reduced to within the limits of 0.01 to 0.05 pct.

Prior to casting, the melts were briefly stirred and then centrifugally cast into investment molds yielding four rectangular bars, 3/16 x 1/4 in. x about 4 1/2 in. long.

The cast bar stock was homogenized for 75 to 80 hr at 1260°C, in an atmosphere of purified argon, and subsequently water quenched. Metallographic examination of the homogenized stock showed that it was free from microsegregation. Chips were obtained from the tops and bottoms of the homogenized bars for chemical analyses, the results of which are shown in Table II for the tungsten alloys, and in Table III for the molybdenum alloys.

### Transformation Studies

**Preliminary Aging Tests:** Specimens of the homogenized Co-Cr-W and Co-Cr-Mo alloys were heat treated in purified argon for 100 hr at temperatures in the range of 700° to 1175°C, and water quenched to room temperature. Temperatures at 25°C intervals, within the above-mentioned temperature range, were selected for the heat treatments. The specimens were then examined metallographically to determine the phases present. Throughout this investigation, the phases were identified metallographically using the etching reagents and procedures described in an earlier paper.<sup>1</sup> No new phases were encountered in these systems. The results of this examination, plotted as a function of temperature and composition, gave an indication of the effects of the third element upon the reactions occurring in these alloys.

The  $\alpha$ - $\beta$  transformation in these alloys is very sluggish, presumably because the energy change involved in this transformation is small. Consequently, the results obtained from these tests show only trends and serve to block in regions for further study. Later in this paper a description is given of

an experimental technique used to eliminate the factor of sluggishness.

Large amounts of a precipitate were found in the

high molybdenum alloys where  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 32$ .

Microscopic examination suggested that the precipitate might be  $\gamma$  phase ( $\text{Co}_2\text{Cr}_3$ ). This was verified by X-ray diffraction studies. It was also observed that in the high molybdenum alloys the interplanar spacings of  $\alpha$ ,  $\beta$ , and  $\gamma$  were expanded about 1 to 1 1/2 pct over those of a Mo-free alloy. Hence, it is concluded that in the Co-Cr-Mo alloys, the molybdenum is in solution in both  $\gamma$  and the two Co-rich terminal solid solutions,  $\alpha$  and  $\beta$ .

Difficulties were encountered in identifying the matrix structures of the 7.92 and 11.65 pct Mo alloys

with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} =$  approximately 32. These two

alloys, when aged at 1025°C and below, showed massive  $\gamma$  and also clouds of fine  $\gamma$  precipitate which masked the matrix and prevented metallographic identification. When these alloys were pre-aged at 1100°C for 60 hr and then aged at 1025°C and below, the  $\gamma$  phase coming out of solution during the second aging treatment tended to deposit on the massive  $\gamma$  particles already present. This pre-aging treatment resulted in a substantial increase in size and decrease in number of precipitated particles present when the alloys were aged at temperatures below 1025°C. Thus, the matrix phases could be identified metallographically, but the relative amounts could not be estimated.

On the basis of these preliminary tests, the approximate  $\alpha$ - $\beta$  transformation range for the alloy containing 7.92 pct Mo appears to be from 960° to 990°C.; the range for the 11.65 pct alloy is approximately 980° to 1010°C.

**Accurate Determination of the Transformation:** All of the preliminary or blocking-in aging treatments on the W and Mo-bearing ternary alloys were carried out on stock which had previously been quenched from the homogenizing temperature. This

treatment produced prior structures of  $\alpha$  plus a martensitic-type  $\beta$ . Because the  $\alpha$ - $\beta$  reaction is sluggish, equilibrium conditions are not attained in these alloys in 100 hr of aging. The results of reaction-rate tests made during the early work on Co-Cr binary alloys<sup>1</sup> indicated that 30 days or more would be required to reach equilibrium in the 80 pct Co-20 pct Cr alloy at 808°C. It is certainly not feasible to treat specimens isothermally for this length of time in determining phase diagrams.

If an aging time less than that required to attain equilibrium is used, the transformation temperature will appear to be lower or higher than the equilibrium values depending on whether the prior structures of the specimens were  $\alpha$  or  $\beta$ , respectively. However, this factor of undercooling or overheating can be eliminated, while still using relatively short aging times, if the following procedure is used:

Specimens with all- $\beta$  and all- $\alpha$  structures are aged simultaneously at various temperatures in and near the transformation temperature range, as determined by the preliminary blocking-in tests. Metallographic examination shows the phases forming in each specimen at particular aging temperatures; consequently, those phases which are in equilibrium at a given temperature are determined. Thus, by eliminating the factor of sluggishness, both the upper and lower limits of the  $\alpha$ - $\beta$  transformation range for each alloy are defined quite accurately.

The simultaneous aging of all- $\alpha$  and all- $\beta$  specimens in order to determine the limits of the transformation will hereafter be referred to as the "up-and-down" treatment. This is carried out as follows:

Small specimens are cut from the bar stock that has been previously transformed to  $\beta$ . All- $\alpha$  specimens are obtained by pretreating homogenized stock for a minimum of 3 hr at 1200°C in an argon atmosphere; these specimens are transferred directly from the pretreating furnace to the aging furnace. As the transfer is made, the cold  $\beta$  specimen is placed in the hot Alundum boat containing the  $\alpha$  specimen. A

stainless steel block, heated to 1200°C, is used during the transfer to conserve heat in the Alundum boat and the  $\alpha$  specimen, so that the temperature of the  $\alpha$  specimen does not drop below the aging temperature. The pair of specimens is aged isothermally in an argon atmosphere for 100 hr at the temperature being investigated, and then water quenched.

The first step in the up-and-down treatment is the preparation of specimens with  $\beta$  structures. The preliminary blocking-in tests indicated that all- $\beta$  or  $\beta$ + $\gamma$  structures could be obtained in 7 of the 14 alloys studied by aging for 100 hr at particular temperatures. Bars of these alloys were aged for 150 hr at the selected temperatures to insure completion of the transformation to  $\beta$ . The predominately  $\beta$  structures of these bars were verified by metallographic examination of the top and bottom of each bar. The two alloys which required double-aging treatments to agglomerate the  $\gamma$  phase were not amenable to the up-and-down type of test, so no attempts were made to produce  $\beta$  structures in these alloys.

In the preliminary tests, 100-hr aging treatments failed to produce all- $\beta$  or  $\beta$ + $\gamma$  structures in five of the alloys (1.05, 3.02, and 5.94 pct W, and 0.95 and

4.04 pct Mo with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = \text{approximately } 20$ ).

This undoubtedly resulted from the sluggishness of the transformation at relatively low temperatures. All of the alloys mentioned contained a minimum of about 2 to 5 pct  $\alpha$  after aging, with the exception of the 5.94 pct W alloy; in this, the  $\alpha$  structure predominated at all of the aging temperatures.

Tests were made to determine whether cold working prior to aging would speed up the transformation from  $\alpha$  to  $\beta$ . It was found that cold reducing 15 pct before aging at the appropriate temperatures for 75 hr resulted in structures which were essentially  $\beta$  phase in the five sluggish alloys. Consequently,  $\beta$  stock for these alloys was prepared in this manner. To eliminate the possible influence of prior history on the transformation, the all- $\alpha$  specimens were also prepared from cold-worked stock.

After metallographic examination of the up-and-down test specimens, a comparison of the prior structures was made with those observed after aging.

\* Corrected to  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 20.0$  or 32.0.

This showed which phases were forming at the aging temperature. Knowledge of the phases in equilibrium followed directly from a comparison of the new phases forming in each specimen of a pair aged at any one temperature. Knowing which phases are in equilibrium at a given temperature permits locating the  $\alpha$ - $\beta$  transformation range with respect to this temperature.

For each of the alloys investigated, a plot was made of the up-and-down structural data as a function of the isothermal aging temperature. For convenience, the amounts of  $\alpha$  present in the specimens with both  $\alpha$  and  $\beta$  prior structures were plotted, as well as the amount corresponding to the average or equilibrium structure. For each alloy, the temperatures represented by the intersection of a straight line passed through the equilibrium points with the ordinates corresponding to 0 and 100 pct  $\alpha$  have been taken as the lower and the upper limits, respectively, of the transformation range. These temperatures are summarized in Table IV.

The alloys with the two highest molybdenum contents and with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 32$  were not amenable to the up-and-down type of treatment, because double-aging treatments were necessary in those alloys to permit identification of the matrix phases. Consequently, the data for these two alloys were obtained from only the preliminary tests in which the double-aging treatments were used.

It was intended that these studies would be made on alloys with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 20.0$  and 32.0. As shown in the chemical analyses in Tables II and III and summarized in Table IV, the alloys did not exactly meet these requirements. Corrections were applied

to the experimental data to adjust for the slight variations in chromium content.

These corrections were determined in the following manner: The value of  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}}$  was calculated for each alloy. (These values are given in Table IV.) Then, by referring to the Co-Cr binary diagram,<sup>1</sup> the transformation temperature of a binary alloy with that chromium content was noted. The difference between this temperature and the transformation temperature for the 20.0 or 32.0 pct Cr alloy, as the case might be, was taken as the correction to be applied algebraically to the transformation temperature of the ternary alloy under consideration. As an example, consider alloy DAA

(Table IV) which has a value of  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 19.7$ .

The limits of the  $\alpha + \beta$  field of a binary alloy with 19.7 pct Cr are 5°C lower than the limits for one containing 20.0 pct Cr. Then 5°C is added to the experimental transformation limits for alloy DAA to give the corrected transformation range shown in the last column in Table IV.

In the same manner the temperatures of the individual up-and-down tests and the preliminary aging tests were corrected so that the observed

structures represent alloys with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} =$  exactly

20 and 32. The corrected values are plotted in Figs. 1 to 4, showing the effect of tungsten or molybdenum upon the  $\alpha + \beta$  temperature range in these alloys. After these differences in chromium content are compensated for, the data more clearly show the

Fig. 1—Effect of tungsten on alpha plus beta temperature range and gamma precipitation in Co-Cr-W alloys with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 20.0$ .

Fig. 2—Effect of tungsten on alpha plus beta temperature range and gamma precipitation in Co-Cr-W alloys with  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 32.0$ .

effects of tungsten and molybdenum upon the transformation.

It would be desirable to make corrections also for the small amounts of nitrogen, iron, and nickel present in these alloys as impurities, inasmuch as the effects of these elements have been determined.<sup>2</sup> However, these additional corrections were not made for reasons covered in the discussion.

**Gamma Precipitation:** All of the preliminary and up-and-down aged specimens were repolished and etched so that  $\gamma$  phase, if present, could be detected metallographically. Additional aging tests were required for those alloys in which the  $\alpha$ - $\beta$  transformation and the limit of  $\gamma$  solubility are found in different temperature ranges. All of these supplementary tests were made on homogenized stock cold worked to a reduction of 15 pct to accelerate the precipitation of  $\gamma$  phase. The first specimens were aged for 50 hr; all others were aged 100 hr so that the data obtained from these are comparable with the results from those up-and-down specimens which had been cold worked.

Corrections for variations in chromium were applied to these data, using the method described earlier in this paper. These temperatures are summarized in Table V and indicate the temperature at which  $\gamma$  starts to precipitate in each alloy. The corrected data are also plotted in Figs. 1 through 4.

Thus, Figs. 1 through 4 show the influence of tungsten and molybdenum on both the  $\alpha$ - $\beta$  transformation and the precipitation of  $\gamma$  in Co-Cr alloys with

$$\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}} = 20 \text{ and } 32.$$

### Discussion of Results

As mentioned earlier in this paper, it would have been desirable to apply corrections to the data to compensate for the traces of iron, nickel, and nitrogen present as impurities. However, when attempts were made to apply such corrections, inconsistent results were obtained. For example, in some cases after these corrections were made, the lower limit of the  $\alpha$ + $\beta$  region was above the upper limit. This, of course, is impossible. One explanation for this might be the inaccuracy of the ternary diagrams at these small percentages (traces) of the third element. It is also possible that interactions occur between the traces of iron, nickel, or nitrogen and the molybdenum or tungsten present in the alloys being studied, in which case the correction factors obtained from the ternary diagrams would not apply. Consequently, in Figs. 1 through 4 no corrections have been made for impurities in the alloys.

In the up-and-down tests on one of the molybde-

num alloys (alloy MF with 3.52 pct Mo and  $\frac{\text{Cr} \times 100}{\text{Co} + \text{Cr}}$

$= 31.0$ ), two pairs of specimens appeared to have inconsistent structure ratings. These two pairs were treated isothermally at temperatures 2°C apart, the second test intended as a check of the first. Normally after an up-and-down aging treatment in the  $\alpha$ - $\beta$  transformation range for each pair, the specimen with an  $\alpha$  prior structure contains more  $\alpha$  than the one which had a  $\beta$  prior structure. Under ideal conditions in which equilibrium is attained, the two would have the same amount of a given phase. In these tests, after aging, the specimens which were

formerly  $\alpha$  contained much less  $\alpha$  than did the specimens which were formerly  $\beta$ . However, it was found that in each instance the specimen which was formerly  $\alpha$  contained much less  $\gamma$  after aging than did the specimen which was formerly  $\beta$  phase. This large differential in the amount of  $\gamma$  phase which precipitated means that the composition of the matrix phase for the two specimens of each pair was different. Since the  $\gamma$  phase is rich in chromium ( $\text{Co}_2\text{Cr}_3$ ), the matrix of the specimen with the most  $\gamma$  precipitate was lower in chromium content than that of the other. The Co-Cr binary diagram shows that as the chromium content is lowered, the transformation temperature range is also lowered. Thus, since the two specimens were aged at the same temperature, the specimen which was formerly  $\alpha$  was lower in its transformation range, and hence contained more  $\beta$ .

One of the objectives of this investigation was to learn the reason for the inconsistent high temperature mechanical properties of Vitallium. Erratic data obtained while determining the temperatures at which  $\gamma$  starts to precipitate in the W and Mo-bearing ternary alloys may be associated with these inconsistent properties. For example, in alloys of nominally the same composition, the temperature at which the first metallographic trace of  $\gamma$  was observed varied by as much as  $120^\circ\text{C}$ . These data have been summarized in Table V.

In Figs. 1 through 4, the  $\gamma$  precipitation studies at most of the concentration levels of the ternary addition element were made on two and occasionally three alloys of approximately the same composition. In every instance, the up-and-down tests were made on only one of the alloys at a given concentration level. In plotting the results of the preliminary, up-and-down, and  $\gamma$ -precipitation aging tests, the abscissas represent the ternary alloy content of that

alloy actually used for a specific heat treatment. In some instances, the alloy contents are so close as to lead to confusion of structural data of one alloy with that of another. In such instances, one of the alloys has been identified by the code used in the tables of chemical analyses and in the tables summarizing the results of the transformation and the  $\gamma$ -precipitation studies.

For example, in Fig. 3, three alloys are represented with approximately 4 pct Mo, one at 4.04 pct and others at 3.93 and 3.91 pct. Information obtained using the alloy containing 3.93 pct Mo has been labeled "alloy MBD" to distinguish it from data pertaining to the alloy with 3.91 pct Mo (alloy MBE). As shown in the figure and summarized in Table V, the temperature at which  $\gamma$  starts to precipitate in these three alloys varies considerably. It ranges from about  $760^\circ\text{C}$  for alloy MB (4.04 pct Mo) and  $770^\circ\text{C}$  for alloy MBD (3.93 pct) to about  $840^\circ\text{C}$  for alloy MBE (3.91 pct).

Undoubtedly these variations in  $\gamma$ -precipitation characteristics are influenced either by trace elements (impurities) or by prior mechanical or thermal history. The factors responsible for these variations in the ternary alloys may also be responsible for the inconsistent mechanical properties of Vitallium, because of the influence of  $\gamma$  precipitation on mechanical properties. It is planned to study this more thoroughly in the next phase of this investigation.

### Summary

Results of this investigation show that tungsten has little effect upon the  $\alpha$ - $\beta$  transformation temperature range, while molybdenum tends to raise it. Both elements tend to promote the formation of  $\gamma$  phase, molybdenum being more potent in this respect than tungsten.

It is concluded from X-ray diffraction studies that in the Co-Cr-Mo alloys, the molybdenum is in solution in both  $\gamma$  and the two Co-rich terminal solid solutions,  $\alpha$  and  $\beta$ .

Anomalous results were obtained in  $\gamma$ -precipitation studies of alloys of nominally the same composition. It seems likely that the  $\gamma$ -precipitation characteristics of these alloys are influenced either by impurities or by prior thermal or mechanical history.

When attempts were made to correct the  $\alpha$ - $\beta$  transformation data to compensate for iron, nickel, and nitrogen present as impurities, inconsistent results were obtained; consequently, it was impossible to make the corrections. One explanation is the inaccuracy of the ternary diagrams in the regions of traces of the third element. Also, not to be overlooked are possible interactions between the trace elements and the molybdenum or tungsten present in the alloys investigated.

### Acknowledgment

The authors wish to express their appreciation to the sponsoring agency, Materials Section, Office of Naval Research, U. S. Navy Department, for permission to publish these results. They also wish to thank the various members of the Battelle staff who assisted in the investigation. Special thanks are due to H. W. Russell and G. K. Manning, under whose supervision this research investigation was conducted.

# Isothermal Transformation and Properties of a Commercial Aluminum Bronze

by A. H. Kasberg, Jr. and David J. Mack

The transformation characteristics are found to resemble a similar binary alloy. The differences are due to the alpha iron particles. While strength properties of the isothermally transformed alloys are high, ductility is low, resulting in high notch sensitivity. The elastic modulus can be varied widely and correlates with strength. Abnormal grain growth sometimes occurs.

A CONSIDERABLE amount of work has been done on the isothermal transformation of high purity aluminum bronzes using the methods pioneered by Davenport and Bain.<sup>1</sup> The first isothermal study of these alloys was made by Smith and Lindlie,<sup>2</sup> but more recently Mack<sup>3, 4</sup> and Klier and Grymko<sup>5</sup> have continued the work. In commercial aluminum bronzes, one or more elements are always added to refine the  $\beta$  grain size and to improve the mechanical properties. The effect of these elements on the isothermal transformation has not been reported in the literature.

No systematic study of the properties of isothermally transformed aluminum bronzes has apparently been reported, although adequate information is available on their properties after more conventional heat treatments. The fact that a eutectoid alloy will reject face-centered cubic  $\alpha$  during isothermal transformation at appropriate temperatures<sup>2, 3</sup> warrants investigation of the properties of such structures. Another cogent reason for determination of properties is the fact that the modulus of elasticity of the eutectoid alloy varies widely with the nature of the heat treatment.<sup>6</sup>

Preliminary experiments<sup>7</sup> indicated that a high purity eutectoid alloy would not give reproducible results in property determinations because of ex-

cessive  $\beta$  grain growth during heat treatment, a single  $\beta$  grain frequently occupying the entire cross-section of a standard test bar. For this reason a commercial aluminum bronze containing iron as a grain growth inhibitor was used.

The isothermal transformation diagram of the alloy was first determined. On this basis, the heat treatments necessary to produce representative structures were selected and the properties determined.

## Material

A commercial alloy (Ampco Grade 20) of the following composition was used: Cu, 83.68 pct; Al, 12.31 pct; Fe, 3.68 pct; Ni, 0.28 pct; and Mn, 0.03 pct. This alloy proved to be very close to the eutectoid composition and may be compared with the accepted value<sup>8</sup> of 11.8 pct Al in the binary Cu-Al system. Comparison is valid only because of the "negative replacement effect" of the iron.<sup>9</sup> Since traces of excess  $\gamma_2$  are present, the alloy is slightly hyper-eutectoid. The material was received in the form of  $\frac{3}{4}$  in. round, hot extruded bars. Specimens of approximately  $\frac{1}{8}$  in. thickness were cut from this stock and drilled to allow suspension in the salt bath.

The structure of the as-received material varied from 5 to 40 pct  $\alpha + \gamma_2^*$  in a matrix of  $\beta'$ . The amount of  $\alpha + \gamma_2$  present was dependent upon the  $\beta$  grain size of the extruded material. The coarse grained portions did not form as much  $\alpha + \gamma_2$  as did

A. H. KASBERG, JR. is associated with Westinghouse Electric Corp., Pittsburgh, and D. J. MACK, Member AIME, is Professor, Dept. of Mining and Metallurgical Engineering, University of Wisconsin, Madison, Wisc.

Discussion on this paper, TP 3147E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, Jan. 15, 1951. Detroit Meeting, October 1951.

This paper represents part of a thesis by A. H. Kasberg, Jr. submitted in partial fulfillment of requirements for the degree of Master of Science, Metallurgical Engineering, to the Graduate Faculty of the University of Wisconsin.

\* The phases encountered in the binary Cu-Al alloy are as follows:

- $\alpha$ —Face-centered cubic copper-rich terminal solid solution.
- $\beta$ —Body-centered cubic intermediate solid solution stable above the eutectoid temperature range.
- $\beta_1$ —Ordered body-centered cubic  $\beta$ .
- $\beta'$ —Martensite structure, Al < 13 pct, nearly hexagonal close-packed.
- $\beta''$ —Appears as rosettes in  $\beta'$ . The  $\beta'$  of Smith and Lindlie.<sup>2</sup>
- $\gamma_2$ —Intermediate aluminum-rich solid solution.  $\gamma$  brass structure.
- $\gamma'$ —Martensite structure, Al > 13 pct, hexagonal close-packed.

the fine grained portions upon cooling after extrusion. The grain size was a function of the amount of work the material received in the extrusion process, the first metal to be extruded from a billet being much less drastically worked than the last metal to be extruded and hence having a coarser grain size.

Some centrifugal sand castings of this same material were also supplied by Ampco Metal, Inc., for property determination. The analyses of the extruded and cast material were nearly identical.

### Isothermal Transformation

All experimental procedures employed were those commonly used in work of this nature. The  $\frac{1}{8}$  in. wafer specimens employed for the determination of the isothermal transformation diagram were soaked 20 min at 800°C in air and quenched in the isothermal salt bath, followed by water quenching to stop the reaction. This soaking time and temperature allowed complete homogenization and no  $\beta$  grain growth was observed in specimens that contained no stress concentrators. This will be discussed in the section on abnormal grain growth. The experimental results are described in the following sections.

**Iron-rich Particles:** In view of the importance of the iron in controlling the  $\beta$  grain size and because very little material has been published concerning the behavior of the iron-rich phase, a study was made of the behavior of these particles during different thermal treatments.

These iron-rich particles have been variously defined as, "intermetallic compound,"  $\text{FeAl}_3$ , and a eutectic of  $\text{Al-FeAl}_3$ . The most accurate description of them in the literature was made by Strauss.<sup>13</sup> On the basis of much indirect evidence it was assumed that these iron-rich particles were, in actuality, b.c.c.,  $\alpha$  iron. After this hypothesis had been formulated, the authors ran across a little known paper by Yutaka<sup>14</sup> on the ternary  $\text{Cu-Al-Fe}$  system which completely confirmed the hypothesis that these "iron-rich" particles were merely  $\alpha$  iron.

Specimens were held at various temperatures in the  $\beta$  region to observe the equilibrium conditions attained between the  $\alpha$ -iron particles and the  $\beta$  matrix. Maximum solubility of the particles occurs at about 975°C. Fig. 1\*\* shows the particle distribution obtained by holding at 975°C for 20 hr, quenching in water, reheating to 800°C for 20 min and quenching in a salt bath at 315°C for a period of 48 hr, followed by a water quench. No reaction took place in the  $\beta$  matrix at the 315°C holding temperature except for the precipitation of the  $\alpha$ -iron particles. The large rounded particles indicate the amount that was not in solution at 975°C, and the small particles indicate the amount that came out of solution during the treatment at lower temperatures. The relative number of fine particles is a measure of the difference in solubility between 975° and 315°C. The arrangement of the fine particles in straight lines suggests that the particles nucleate along preferred crystallographic planes.

Fig. 2 is shown for comparison. This specimen was soaked at 800°C for 20 min and quenched in the salt bath at 315°C for 48 hr. The relative number of fine particles indicates the amount of the iron-rich phase in solution at the start of the isothermal transformations.

Fig. 3 shows the equilibrium structure attained by

\*\* Unless stated to the contrary, all specimens were etched with the ferric nitrate etch described in ref. 3.

holding for 120 hr at 550°C. The dark etching phase is  $\gamma_2$ , the light areas are  $\alpha$  and the  $\alpha$ -iron particles are an intermediate gray shade. It should be noted that the  $\alpha$ -iron particles are concentrated in the  $\alpha$  phase. At lower magnifications this causes the  $\alpha$  phase to have a mottled appearance.

The specimens held at temperatures in the  $\beta$  region were examined for grain growth. It was found that the  $\alpha$ -iron particles effectively inhibit normal grain growth for periods of 1 hr at temperatures up to 900°C.

The  $\alpha$ -iron particles apparently cause an age-hardening phenomenon when specimens are quenched from the soaking temperature of 800°C to sub-eutectoid temperatures. Fig. 12 shows a plot of hardness vs. holding time for constant temperature and is representative of the sequence of changes at all isothermal transformation temperatures. From the previously noted change in solubility of the  $\alpha$ -iron particles with temperature, it is believed that this increase in hardness, before the eutectoidal decomposition of the  $\beta$  phase occurs, is due to the precipitation of the  $\alpha$ -iron particles.

**Eutectoid Temperature Range:** The eutectoid transformation in this case is of the binary eutectoid type occurring in a three-component system. Hence, it possesses one degree of freedom and can occur over a temperature interval. The values of 576° to 592°C obtained for this temperature interval by heating curves are probably high due to thermal hysteresis. The metallographic determination gave results slightly lower than these values, but definite start and finish temperatures could not be established. Cooling curves were not taken because the alloy undercools badly. An error of 5°C due to hysteresis seems reasonable. The eutectoid temperature determined for this alloy is slightly higher than the values determined for the binary Cu-Al alloy of 556°C<sup>7</sup> to 565°C<sup>2</sup>.

**Isothermal Transformation:** An orderly pearlite reaction such as is usually found in the high purity alloys was not observed in this alloy in the extruded form, but commonly occurs in castings. Small areas sometimes develop a uniform lamellar structure, but most of the decomposition is by a rhythmical or alternate precipitation of  $\alpha$  and  $\gamma_2$ .<sup>†</sup> This results in an acicular, bainite-appearing product which may have, in fact, morphological resemblance to bainite because it develops out of concentration gradients in the  $\beta$  resulting from a pre-eutectoid precipitation. Fig. 4 illustrates this type of reaction, in which the pre-eutectoid rejection of  $\alpha$  is complete and  $\gamma_2$  is precipitating along the Widmanstätten planes giving a feathery, indistinct structure. The time-temperature-transformation diagram is shown in Fig. 5.

A few comments on the reaction at specific temperatures follow:

**545°C:** The reaction is nucleated by the iron-rich particles, the pre-eutectoid rejection of  $\gamma_2$  starting after 100 sec. The precipitation of  $\gamma_2$  apparently sets up a concentration gradient and at about 2 min a rhythmical precipitation of  $\alpha$  and  $\gamma_2$  begins. A few small areas develop a lamellar structure, but the presence of iron particles and concentration gradients interfere with its development. Fig. 6 shows the equilibrium structure of lamellar areas and coarse aggregate. The mottled appearance of the  $\alpha$  phase is due to the iron-rich particles, see Fig. 3.

<sup>†</sup> The term, "discontinuous precipitation" has been avoided because the authors believe it is commonly used when a recrystallization of the matrix occurs, and this does not happen here.

Fig. 5—Time-temperature-transformation diagram.

**500°C:** The eutectoid reaction is now preceded by the rejection of  $\alpha$  along the  $\beta$  grain boundaries and in a Widmanstätten pattern within the grains. The reaction apparently proceeds in a pattern similar to that proposed for the bainite reaction by Hultgren<sup>10</sup> and the similarity to bainite is apparent in Fig. 4. At this temperature the reaction is nucleated by both the grain boundaries and iron-rich particles.

**395°C:** The reaction is similar to that at higher temperatures but the time required is much longer and the resulting structure is finer. The nucleation and growth of the fine Widmanstätten  $\alpha$  structure takes place from both the grain boundaries and iron-rich particles. The  $\gamma_2$  areas develop in the aluminum-rich areas between the Widmanstätten plates. Fig. 7 shows the final structure attained at this temperature. It is apparent that the structure is primarily determined by the Widmanstätten rejection of  $\alpha$ .

**Effect of  $\beta$  Grain Size:** Specimens of the finest and coarsest uniform  $\beta$  grain sizes were transformed at 500°C. The fine grain specimens were obtained from the most drastically worked end of the extruded rod and had a  $\beta$  grain size of less than 0.010 mm. The coarse grained specimens were obtained by heating at 975°C for 20 hr and had a  $\beta$  grain size of about 4 mm. The start of the transformation for the fine grained specimen was found to be 30 sec at 500°C, the time required for the transformation to start in the large grained specimen being 300 sec. The maximum influence of grain size on the time required for transformation between grain size 0.010 and 4.0 mm is a factor of 10 and is similar to the effect found in Fe-C alloys.<sup>11</sup> The time-temperature-transformation curves were determined for two grain sizes, 0.010 and 0.090 mm. Both curves are shown for comparison in Fig. 5.

**Martensite Reaction:** It was apparent from the thermal characteristics of the martensite reaction in this aluminum bronze that it is endothermic while the martensite reaction in steel is exothermic. The slope of the time-temperature cooling curve for the aluminum bronze is the same before and after the martensite reaction.

The value obtained for the  $M_s$  temperature was 270°C as indicated in Fig. 5. This compares with an  $M_s$  temperature of 370°C for the high purity binary alloy. Examination of the  $\beta'$  structure by polarized light on longitudinal sections cut from the extruded bars showed some preferential orientation of the  $\beta$  phase.

**Abnormal Grain Growth:** Abnormal grain growth was encountered in this study of the isothermal

transformation of a commercial aluminum-bronze. Large grains developed during isothermal transformation at temperatures of 450°C or lower. The grain growth occurred in the retained  $\beta$  phase before the martensite reaction started at a temperature of 270°C. The grain growth was apparently nucleated by mechanically induced interruptions in the normally symmetrical stress pattern resulting from thermal contraction during quenching in the isothermal bath.

Investigation of this phenomenon showed that extruded specimens transformed at temperatures higher than 450°C showed no evidence of grain growth, since quenching stresses were not large enough. Specimens transformed at 450°C showed that grain growth had started at mechanical stress concentrators, Figs. 8 and 9. At this temperature the isothermal grain boundary reaction started in about 10 sec, which stopped the grain growth. Specimens that were quenched to lower temperatures or directly to room temperature showed extensive grain growth, Fig. 10. The structure within the large grains exhibits martensite needles that extend the full width of the grain, indicating that the grain growth was complete before the martensite start temperature of 270°C was reached.

Only specimens with eccentrically positioned stress concentrators showed abnormal grain growth. In specimens with drilled holes at or near the center there was no abnormal grain growth even when a dull drill was used. In this case normal recrystallization occurred in the cold-worked area around the hole, but this grain growth was not abnormal. The sand-cast specimens provided an excellent illustration of the effect of the nonuniform stress pattern on abnormal  $\beta$  grain growth. They were heat treated as-cast in the irregularly shaped bars and without exception showed very large  $\beta$  grains; the extruded specimens were heat treated as uniform cylinders and showed no abnormal grain growth unless internal seams were present to provide the stress concentration. The sand-cast specimens showed abnormal grain growth at all isothermal temperatures.

*Discussion:* The isothermal transformation of this alloy was essentially the same as that encountered in binary alloys.<sup>2, 3, 5</sup> The primary differences are: the raising of the eutectoid temperature and its expansion into a three-phase field; the lowering of the martensite start temperature; and the effect of the iron-rich particles in nucleating the decomposition and interfering with the development of a uniform pearlitic structure.

The coarsest structures were obtained at the highest transformation temperature, and the structures became progressively finer as the transformation temperature was lowered. This was to be expected due to the decrease in diffusion rates with a decrease in temperature.

The  $\beta''$  rosettes observed by Smith and Lindlie<sup>2</sup> and Mack<sup>3</sup> in high purity eutectoid Cu-Al alloys were not observed in this alloy.

The presence of an ordering reaction or the presence of  $\gamma'$  in the partially transformed specimens was not determined since an X-ray diffraction analysis was not made.

Properties

**Experimental Procedure:** The extruded rod was cut to pieces 5½ in. in length, every third specimen being 6½ in., thus allowing a 1 in. section for removal for metallographic examination and hardness determination. The specimens were heat treated in groups of three. They were soaked at 800°C for 30 min in air and then quenched in the isothermal salt bath held at various subeutectoid temperatures. Specimens that had completely transformed in the salt bath were then air-cooled to prevent cracking, since structures composed of  $\alpha$  and  $\gamma_2$  are very brittle. Other specimens held for intermediate time intervals, thus allowing only partial transformation, were quenched in cold water to arrest the transformation.

A dynamic modulus of elasticity was then determined on each cylindrical heat-treated specimen using it as a "free-free" beam, vibrated at its natural frequency. This dynamic testing machine was designed and built by W. T. Thomson, of the Mechanics Department, University of Wisconsin.

After dynamic modulus determination the cylindrical specimens were machined to standard 0.505 in. tensile bars and pulled in a universal testing machine. The static modulus of elasticity was obtained by plotting the stress-strain curve and taking

Fig. 11—Yield strength as a function of the modulus of elasticity of Ampco 20.

the slope of a tangent drawn at one third the yield strength (based on 0.5 pct elongation). This point was chosen since it would approximate the allowable working stress in this alloy in service. The results of the property determinations are shown in Table I.

**Discussion:** The stress-strain curves for these aluminum bronze structures are continuous curves, but at higher values of hardness and strength the lower portion of the curve approaches a straight

line. When the yield strength is chosen at 0.5 pct elongation, the yield strength is a function of the modulus of elasticity as shown in Fig. 11.

The physical properties are plotted as a function of structure in Figs. 12 and 13 for an isothermal transformation temperature of 400°C. At 100 sec the pre-eutectoid rejection of  $\alpha$  has started and an apparent age-hardening reaction due to the iron phase present begins. The hardness and tensile strength increase but the elastic properties remain fairly constant. At about 5000 sec the eutectoid reaction of  $\beta \rightarrow \alpha + \gamma_2$  begins and hardness, strength and elastic properties increase and approach a maximum when the reaction is about 60 pct complete. At this point the  $\alpha + \gamma_2$  aggregate apparently forms a continuous path through the structure. The plastic properties (i.e., elongation and reduction in area) decrease with a further increase in holding time and drop to zero shortly after the eutectoid reaction starts.

The structures obtained at the lower transformation temperatures are finer than the high temperature structures and give a better combination of properties. The high temperature structures appear to be very sensitive to notches and all such specimens failed in tension at the gage marks. Some of the specimens treated at lower temperatures also failed at gage marks. The result of this notch sensitivity is a wide spread in the experimental results.

The agreement between values of the modulus by the dynamic method and the static method is very good and most discrepancies can be correlated to the shape of the stress-strain curve.

Because of the bad effect of the abnormal grain growth on properties and the fact that this abnormal grain growth will occur whenever a change in section size exists, the adaptation of isothermal transformation to commercial heat treatment of this particular aluminum bronze seems out of the question. Any improvement in properties that might be obtained by isothermal treatment would be masked or endangered by the omnipresent possibility of abnormal grain growth.

### Summary

1—The change in solubility of the  $\alpha$ -iron particles with temperature has been shown to cause an age-hardening effect during subsequent isothermal holding. The iron particles are effective in preventing  $\beta$  grain growth for periods up to 1 hr at 900°C.

2—The eutectoid transformation occurs over a temperature range (576° to 592°C) showing this aluminum bronze behaves as a true ternary alloy.

3—The isothermal transformation characteristics do not differ much from those of the binary Cu-Al alloy. Lamellar pearlite does not form readily in the extruded alloy but is common in the cast material. The major portion of the decomposition of  $\beta$  is by

Fig. 13—Percentage transformation, percentage elongation in 2 in., and ultimate tensile strength vs. holding time at 400°C.

rhythmic or alternate precipitation of  $\alpha$  and  $\gamma_2$ . No rosettes of  $\beta''$  were observed.

4—The effect of variations in  $\beta$  grain size on the transformation times is the same as commonly observed for other alloys, fine grains resulting in more rapid transformation.

5—This alloy has a most unusual tendency for abnormal  $\beta$  grain growth in the isothermal bath. The tendency is associated with nonuniform stresses set up in the specimen during the quench into the isothermal bath.

6—While high ultimate tensile and yield strengths can be obtained by isothermal transformation, these high strengths are accompanied by low elongation and reduction in area values which lead to very high notch sensitivity.

7—The modulus of elasticity can be varied over a relatively enormous range by suitable isothermal transformation.

8—The commercial use of isothermal heat treatments for this particular alloy does not seem worthwhile because of the low ductility and susceptibility to abnormal  $\beta$  grain growth.

### Acknowledgments

The writers wish to thank J. F. Klement, Chief Metallurgist of Ampco Metal, Inc., for supplying the material, machining the test specimens, and for his interest and counsel; Kurt F. Wendt of the Engineering Experiment Station; and the Wisconsin Alumni Research Foundation whose grant (RF49:296) to the senior author made this study possible.

# Creep and Stress Rupture Behavior of Aluminum

## As a Function of Purity

by Italo S. Servi and Nicholas J. Grant

**Extensive data of minimum creep rates and rupture times for high purity and commercial aluminum confirm the existence of a transition range from the low temperature-type to the high temperature-type behavior. The data are analyzed in line with the suggested theories of deformation of metals.**

CONSIDERABLY more work has been done on the rupture and creep behavior of commercial alloys than on the less complex, high purity metals. As a result, certain fundamental behaviors are overlooked. One of the lesser known variables affecting the high temperature behavior of metals is the impurity content (or alloy content). Impurities are known to affect strongly the recrystallization temperature, electrical resistivity, and other properties of metals, but the effect on creep and other high temperature mechanical properties has been determined for very few materials.

In view of these facts aluminum appears to be a fairly ideal metal, since it is available in a wide range of purity contents from 99.995+ down through the 2S (99.0 + Al) and 3S (1.2 Mn) grades in small steps. It is highly resistant to oxidation and other surface instabilities, leaving recrystallization and grain growth as virtually the only instabilities. Control of grain size is also well standardized.

Limited data on the creep of aluminum have been obtained by Dushman et al.<sup>1</sup> for high purity aluminum; by Sherby<sup>2</sup> on 2S aluminum of variable grain size; and by Dorn and Tietz<sup>3</sup> on cold-worked 3S aluminum.

### Experimental Procedure

The apparatus consisted of a constant stress, creep testing unit similar to the type described by Hopkin.<sup>4</sup> The specimens were held at temperature for 30 min before loading. The loading time was less than 2 min. Factors affecting the accuracy of the data were: 1—the temperature gradient and control,  $\pm 3^\circ\text{F}$ ; 2—the stress determinations,  $\pm 1.5$  pct; and 3—elongation measurements (1 in. gage),  $\pm 0.001$

in. Three grades of aluminum were tested: 1—high purity (99.995 pct Al), 2—2S (99.3 pct Al), and 3—3S (98.2 pct Al).

The spectrographic analyses of these materials are reported in Table I. The specimens were annealed then electropolished in a perchloric-acetic mixture before testing. Data on heat treatments and grain size obtained appear in Table II.

The entire creep curve was determined for almost all of the tests. A few tests were interrupted after the beginning of the third stage of creep, and in these cases the rupture time was estimated.

### Experimental Results

Constant stress creep-rupture testing gives a much longer, more accurately measurable second stage of creep than constant load testing. This behavior is in agreement with the results obtained by Andrade<sup>5</sup> for lead (see Fig. 1). If the test is run to completion, the third stage of creep appears as soon as stress intensification occurs. In the case of specimens which fail in a ductile manner, the stress intensification begins when the sample starts "necking". This differs from the "high temperature brittle" specimens in which the stress intensification is caused by intercrystalline cracking. These specimens

GRANT, Member AIME, is Associate Professor, Dept. of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

Discussion on this paper, TP 3150E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, March 9, 1951. Detroit Meeting, October 1951.

Fig. 1—Typical creep curves for high purity aluminum obtained from tests made at constant load and at constant stress.

fail by parting along the grain boundaries. Fig. 2 shows typical creep curves for two samples: a high purity aluminum sample which failed in a ductile manner, and a 3S aluminum sample which failed in a brittle manner. In case intercrystalline cracking occurs, as for the 3S sample mentioned above, there is no way of completing the test without entering third stage creep because of the inability to measure the area of sound metal in the cross-section.

All the data are expressed in terms of linear strains and linear strain rates. It was found that the use of true strain and true strain rate did not change the fundamental results and conclusions, and merely shifted the log-log curves of the following figures relative to one another.

The minimum creep rates have been calculated by determining the slope of the straight portion of the creep curves, as indicated by the broken lines of the sample creep curves of Fig. 2.

**Stress Dependence of Minimum Creep Rate:** Fig. 3 shows a plot of the stress vs. the log of the minimum creep rate for high purity aluminum. The data of Dushman et al.<sup>1</sup> are included (dotted lines) for comparison.

Dushman et al.<sup>1</sup> and Kauzmann<sup>6</sup> in applying the Eyring theory of activated complex<sup>7</sup> to the creep of metals predicted that a straight line should be ob-

Fig. 2—Typical creep curves for a specimen which failed in a ductile manner (test No. 34) and a specimen which failed in a brittle manner (test No. 305).

Note the different strain scales.

tained when the stress is plotted vs. the logarithm of the creep rate. This straight line corresponds to an approximation of the hyperbolic sine law. It was shown previously by Grant and Bucklin<sup>8</sup> that the predicted straight line semilog plots of stress vs. minimum creep rate do not exist over wide ranges of creep rate values. However, since the work was done on a very complex, high temperature-type alloy, while Dushman et al. used high purity aluminum and other pure metals, it seemed quite logical to try to confirm Grant and Bucklin's observations by using aluminum of comparable purity. If there is a measurable effect of impurity content on the viscous behavior of metals, this should also be apparent in the creep tests.

Fig. 3—Semilog plot of stress vs. minimum creep rate for high purity, coarse grained aluminum.

Fig. 4—Log-log plot of stress vs. minimum creep rate for high purity, coarse grained and fine grained aluminum.

Fig. 3 for high purity aluminum does lead to the same conclusions as those obtained by Grant and Bucklin on alloy S-590. Smooth curves best represent the experimental points. The straight lines of Dushman et al. simply serve as an approximation over a limited range of creep rate values. While straight line segments would easily be selected, there is no good guide for such selection. A change in slope of the curve, interpreted in terms of Eyring's theory, would indicate an increase in the size of the "units of flow" occurring when the material assumes a more viscous behavior.

Fig. 5—High purity, coarse grained aluminum. Upper: Low temperature test, 400°F. Rupture time, 0.07 hr. Lower: High temperature test, 900°F. Rupture time, 0.33 hr.

Eyring's theory may possibly be applicable to the flow of metals at much slower strain rates, or much higher temperatures, than the strain rates and temperatures investigated. Under these conditions the metal may, in fact, be deforming by a purely viscous mechanism.

The log-log plot of stress vs. minimum creep rate for high purity aluminum is presented in Fig. 4. This plot shows that straight line segments are ob-

Fig. 6—Log-log plot of stress vs. minimum creep rate for 2S and 3S aluminum.

served at all temperatures. However, a change in slope is evident in the 500°F curve, and less clearly in the curves for 400° and 700°F.

These "breaks" locate three transition points, A, B, and C, which were not readily apparent in Fig. 3. Metallographic examination revealed that if the testing conditions are above the line A-B-C, the grain boundaries are stronger than the grains. Under these conditions, the grain boundaries do not make any contribution to the deformation of the

Fig. 7—Change in type of fracture of 2S aluminum as conditions of testing change.

Testing temperature, 900°F. Rupture times (left to right): 0.02 hr (low temperature); 18.4 hr (transition); 41.5 hr, 81.5 hr (high temperature).

Fig. 8—Change in type of fracture of 3S aluminum as conditions of testing change.

Testing temperature, 900°F. Rupture times (left to right): 0.023 hr (low temperature); 0.93 hr (low temperature, approaching the transition); 4.1 hr (high temperature, near transition); 58 hr (high temperature).

sample and only hinder the deformation of the grains (low temperature-type behavior). Below the line A-B-C the grain boundaries are weaker than the grains and contribute to the deformation of the specimen, and do not restrict the deformation of the grains (high temperature-type behavior).

The transition line A-B-C is the line of "equi-cohesion" for grains and grain boundaries. This conclusion is supported by the fact that the fine grained material (dotted lines of Fig. 4) is stronger

Table I. Spectrographic Analysis of the Impurities Contained in Three Grades of Aluminum Used for Creep and Stress Rupture Testing\*

\* The terms "fine grained" and "coarse grained" refer to the grain size of the sample before testing.

Fig. 9—True elongation vs. logarithm of rupture time for high purity, coarse grained aluminum.

than the coarse grained material (solid lines of Fig. 4) in the low temperature region, while the reverse is true in the high temperature region.

It is interesting to note that the very marked grain growth which occurred in tests made at 900° and 1100°F shows up as an instability. This is evidenced by the fact that the slopes of the 900° and 1100°F curves are smaller than the slope of the 700°F curve. However, the same instability is not detectable by inspecting the curves of Fig. 3 (semilog plot).

The fractures of all the specimens were typically ductile, but the shape of the rupture zone changed slightly with the conditions of testing, see Fig. 5.

Fig. 6 shows the log-log plot of stress vs. minimum creep rate for 2S and for 3S aluminum. Straight line segments are obtained at all temperatures, with changes in slope shown at the transition points D, E, F, and G for 2S aluminum and at M for 3S aluminum. The curve at 700°F shows a smaller change in slope than expected, with some evidence that the longest time tests are showing improved resistance to creep. A check of the hardness showed, in fact, that for rupture times greater than 20 hr, there was a hardness increase of about 3 Brinell points.<sup>8</sup>

The ductile nature of the fractures above a line through points D, E, F, and G and above M, and the

Fig. 10—True elongation vs. logarithm of rupture time for high purity, coarse grained aluminum.

brittle intercrystalline fracture below these points is shown in Fig. 7 for 2S aluminum and in Fig. 8 for 3S aluminum.

Metallographic observations revealed more definite evidence of grain boundary flow and grain boundary cracking in the 2S and 3S specimens tested under high temperature conditions. These observations confirm the conclusion that the transitions at D, E, F, G, and M correspond to equicohesion for the grains and grain boundaries.

**Ductility:** A study of the ductility as a function of purity and conditions of testing was made by plotting the true elongation vs. the logarithm of the rupture time, Figs. 9, 10, and 11. The "true elongation" was defined by Grant and Bucklin<sup>9</sup> as the elongation occurring up to the incidence of third stage creep.

Fig. 9 shows that the true elongation data for high purity aluminum tested at 200°, 400°, 500°, and 700°F are scattered around average values. The average value of the true elongation increases as the temperature increases. Fig. 10 indicates that at 900°

Fig. 11—True elongation vs. logarithm of rupture time for 2S and 3S aluminum.

and 1100°F the true elongation of high purity aluminum decreases as the rupture time increases. At these temperatures marked grain growth occurred during testing.

Fig. 11 demonstrates that the true elongation of 2S and 3S aluminum markedly drops at the transition from low temperature-type to high temperature-type deformation. The decrease in true elongation is much sharper for 3S than for 2S. For both materials the decrease in true elongation corresponds to the incidence of intercrystalline cracking.

**Stress Dependence of Rupture Times:** Results

Table III. Calculated and Experimental Transition Temperatures for High Purity, Coarse Grained Aluminum

Fig. 12—Log-log plot of stress vs. rupture time for high purity aluminum.

similar to those shown in log-log plots of stress vs. minimum creep rate (Figs. 4 and 6) were obtained when the logarithm of the rupture time was plotted vs. the logarithm of the stress. Fig. 12 (high purity aluminum) and Fig. 13 (2S and 3S aluminum) show that a series of "breaks" are found for each material investigated. A continuous straight line could be drawn through the 1100°F points of Fig. 13. The curve drawn in Fig. 13 for this temperature is based on the uncertainty of the last point, which was affected by excessive secondary recrystallization.

The log-log plots "stress vs. minimum creep rate" and "stress vs. rupture time" are almost mirror images. This behavior can be explained by assuming that the minimum creep rate is inversely proportional to the rupture time:

$$\text{M.C.R.} = \frac{E_0}{\text{R.T.}} \quad [1]$$

where  $E_0$  is a constant.

As a first approximation all the test results for high purity and 2S aluminum follow eq 1. In fact, a log-log plot of minimum creep rate vs. rupture time gives a band slope  $-1$ , with a reasonably limited scatter (see Figs. 14 and 15). The high temperature points obtained for 3S aluminum deviate from eq 1. The different behavior of these specimens may be ascribed to their comparatively low ductility.

**Transition Stresses and Transition Strain Rates:** The average values of the transition stresses and of the transition strain rates, as determined from the "breaks" in the isothermal lines of Fig. 4 (points A, B, C) and Fig. 6, (points D, E, F, G, M) and from

Fig. 13—Log-log plot of stress vs. rupture time for 2S and 3S aluminum.

the results of metallographic examinations, are plotted vs. the temperature in the semilog plots of Figs. 16 and 17, respectively. The results indicate that: 1—Impurities raise the transition stress for a given temperature. 2—Impurities lower the transition strain rate for a given temperature. 3—The transition stress and strain rate have definite values at temperatures close to the melting point. 4—Below a certain critical temperature, no transition will be observed within a reasonable testing time.

The results of Fig. 16 are in good agreement with the results obtained by Grant and Bucklin<sup>9</sup> for cobalt-base alloys, however, the present experimental results were obtained close to the melting point, whereas considerable extrapolation had been necessary in working with the complex S-590 alloy because creep rupture tests had to be limited to 1800°F (melting point 2450°F). An attempt has been

Fig. 14—Log-log plot of minimum creep rate vs. rupture time for high purity aluminum.

Fig. 15—Log-log plot of minimum creep rate vs. rupture time for 2S and 3S aluminum.

made to compare the experimental results reported above on the transition temperature with the Mott theory of grain boundary slip.<sup>10</sup> According to Mott, viscous flow cannot occur along the grain boundaries below a critical temperature  $T_c$ , which is defined by the equation:

$$T_c = \frac{Q}{R \ln \left( \frac{b \sigma}{x \dot{\epsilon}} \right)} \quad [2]$$

where  $Q$ ,  $b$  are constants associated with the viscous flow at the grain boundaries;  $\sigma$  is the applied stress;  $x$ , the linear grain size;  $\dot{\epsilon}$ , the creep rate; and  $R$ , the gas constant.

Based on Kê's work<sup>11</sup> with 99.991 pct Al, Mott

Fig. 16—Logarithm of transition stress vs. temperature for high purity, coarse grained 2S and 3S aluminum.

calculated the theoretical critical temperature for aluminum and obtained a value of 410°K (277°F) for "normal" creep testing conditions.

The theoretical critical temperatures corresponding to the conditions of testing used in the present investigation have been calculated in a similar way. The results are presented in Table III.

Eq 2 can be re-written as follows:

$$\text{Log } \frac{\sigma}{\dot{\epsilon}} = A + \frac{B}{T_c} \quad [3]$$

where  $\sigma$  is the transition stress, and  $\dot{\epsilon}$  is the transition strain rate for the temperature  $T_c$ .  $A$  and  $B$  are constants proper of the material.  $\frac{\sigma}{\dot{\epsilon}}$  is a measure of the grain boundary viscosity.

Utilizing Mott's values for  $Q$  and  $b$  from eq 2 and expressing the stress  $\sigma$  in psi and the creep rate  $\dot{\epsilon}$  in  $\text{hr}^{-1}$ , the constants  $A$  and  $B$  for aluminum are:  $A = -10.4$  and  $B = 7680$ .

The logarithm of  $\frac{\sigma}{\dot{\epsilon}}$  was plotted vs. the reciprocal of the absolute temperature in Fig. 18. Straight lines were obtained for high purity and for 2S aluminum, in agreement with eq 3. However, the calculation of the constants  $Q$  and  $b$  of eq 2 lead to values which deviate from the values used by Mott. The following results were obtained:

#### 1—High purity aluminum:

$Q = 29,000$  cal per gram-atom  
 $b = 10^{-2}$  cgs units

Fig. 17—Logarithm of transition strain rate vs. temperature for high purity, coarse grained 2S and 3S aluminum.

2—2S aluminum:  $Q = 16,000$  cal per gram-atom  
 $b = 10^{-11}$  cgs units

3—Values used by Mott (based on data for 99.991 pct Al)  
 $Q = 35,000$  cal per gram-atom  
 $b = 20$  cgs units

The results show that Mott's theory of grain boundary slip can be applied to an impure solid solution as well as to a high purity material. The critical temperature,  $T_c$ , is markedly affected by the impurity content.

**Temperature Dependence of Creep Rates:** In the absence of structural instabilities, the slope of the straight lines obtained by plotting the logarithm of the stress vs. the logarithm of the minimum creep rate generally increases as the temperature increases. The data obtained for high purity aluminum (Fig. 4) indicate that this rule applies to this material. However, when marked grain growth occurs (at 900° and 1100°F) the slope of the lines decreases.

The data of Fig. 4 for temperatures from 200° to

Fig. 18—Logarithm of the ratio of transition stress to transition strain rate  $\frac{\sigma}{\dot{\epsilon}}$  vs. the reciprocal of the absolute temperature of testing, experimental and theoretical curves.

700°F were used to determine the creep rates at constant stress levels. These data are not appreciably affected by grain growth. Both low temperature and high temperature points were taken into consideration since the "breaks" are not sharp enough, in the case of high purity aluminum, to affect the approximate value of the temperature coefficient of creep rates.

The logarithm of the minimum creep rates is plotted vs. the reciprocal of the absolute temperature in Fig. 19. Straight lines should be obtained for each stress level, according to Boltzmann's equation:

$$r = A e^{-Q/RT} \quad [4]$$

where:  $r$  is the rate of a process;  $R$  and  $A$  are constants;  $Q$  is the temperature coefficient; and  $T$ , the absolute temperature.

Only two or three points appear in Fig. 19 for each stress level; therefore, the straight lines do not constitute proof of the validity of eq 4. However, if eq 4 is assumed to be valid, it is possible to de-

termine the approximate value of the temperature coefficient  $Q$  for several stress levels. The values so determined indicate that  $Q$  is a function of the stress according to the equation:

$$Q = M + N \log s \quad [5]$$

where:  $M$  and  $N$  are constants and  $s$  is the applied stress.

This is shown in graphical form in Fig. 20 where the logarithm of the stress was plotted vs.  $Q$ . Eq 5 and Fig. 20 are in agreement with the results obtained by Carreker<sup>14</sup> for platinum wire.

The linear relationship observed in the log-log plot of stress vs. minimum creep rate (Fig. 4) and the validity of eqs 4 and 5 are in agreement with the empirical equation:

$$\log r = a + (b/T - c) (\log s + d) \quad [6]$$

where:  $r$  is the minimum creep rate;  $s$ , the stress;  $T$ , the absolute temperature; and  $a$ ,  $b$ ,  $c$ , and  $d$ , the constants of the material.

Eq 6 was suggested by Servi and Grant<sup>12</sup> based on the analysis of the data obtained by Grant and Bucklin<sup>9</sup> and of other published data.

Fig. 20 does not indicate any sharp change of the

Fig. 19—Logarithm of minimum creep rate at constant stress vs. the reciprocal of the absolute temperature for high purity, coarse grained aluminum.

temperature coefficient  $Q$  at the transition from low temperature to high temperature behavior. Such a negative conclusion is not absolute since the determination of  $Q$  can be done only in an approximate way.

**Primary Creep:** Primary creep was studied for coarse grained, high purity aluminum. When the strain was plotted vs. the cube root of the time, an approximately straight line was obtained during the first stage of creep, in good agreement with the results obtained by Cottrell and Aytekin<sup>18</sup> for zinc. As a first approximation this result is in agreement with Andrade's eq 5:

$$l = l_0 (l + \beta t^{1/3}) e^{\beta t} \quad [7]$$

where:  $l$  is the length of the specimen at time  $t$ ;  $l_0$ , a constant (not necessarily the original length of specimen);  $\beta$ , the coefficient of primary creep; and  $k$ , a coefficient of steady state creep.

The stress dependence of  $\beta$  appears to be similar to the stress dependence of the minimum creep rate, as demonstrated in Fig. 21 where the logarithm of

Fig. 20—Logarithm of stress vs. temperature coefficient of strain rate for high purity, coarse grained aluminum.

the stress is plotted vs. the logarithm of  $\beta$  for high purity aluminum tested at 500°F.

The first stage of several creep curves was replotted in other non-conventional ways. Both the log-log and the semilog plots of strain vs. time gave curves of increasing slope. These results indicate that the equations

$$\text{strain} = A t^B \quad [8]$$

and

$$\text{strain} = A + B \log t \quad [9]$$

do not apply to the primary creep of aluminum, at least in the range of temperatures and strain rates investigated.

## Discussion of Results

The results of the present investigation show that the log-log method of plotting creep rate and rupture time data as a function of stress is the most suitable one for analyzing the behavior of aluminum alloys of different purity. The log-log method of plotting reveals structural instabilities, which in the case of aluminum are: 1—the change from low temperature type to high temperature type of deformation, and 2—grain growth.

Change 1 is characterized by the beginning of grain boundary flow. In the case of a high purity material the transition from low temperature to high temperature deformation is revealed by a decrease in creep resistance ("breaks" in the log-log plot of stress vs. minimum creep rate), by metallographic evidence of grain boundary flow, and by the relative strength of coarse and fine grained structures.

In the case of a more impure material the transition also affects the type of fracture which changes from transcrystalline to intercrystalline. The duc-

Fig. 21—Log-log plot of stress vs.  $\beta$ , the coefficient of primary creep, for high purity, coarse grained aluminum tested at 500°C.

Fig. 22—Strength of the grain and strength of the grain boundary as a function of temperature for high purity and impure metals.

tility of the material decreases as a consequence of intercrystalline cracking.

These conclusions are in good agreement with the results and conclusions obtained by Grant and Bucklin<sup>9</sup> for complex cobalt-base alloys. Similar creep and rupture behavior, at least as far as the transition from low temperature to high temperature type of deformation is concerned, has now been shown to prevail for a high purity metal, two more impure metals, and two complex alloys.

The effect of impurities on the creep and stress rupture properties of metals and especially on the transition from low temperature to high temperature behavior can be interpreted by modifying the theory of equicohesion as follows: it is assumed that two intersecting lines are obtained when the hypothetical "strengths" of the grain and of the grain boundary are plotted vs. the temperature (see Fig. 22). The difference in slope between the two lines is greater for an impure material (Fig. 22B) than for a high purity material (Fig. 22A). The high purity material has a wide range of temperatures where the strengths of the grains and of the grain boundaries are not markedly different. For this reason the decrease in creep resistance observed at the transition from low temperature to high temperature behavior is more marked for an impure than for a high purity metal. For the same reason intercrystalline fracture is not observed in a high purity material tested under high temperature conditions.

Moreover, local recovery and grain boundary migration are more likely to occur in a high purity metal; therefore such a material can undergo a large amount of deformation without cracking along the grain boundaries.

A more impure metal is prone to undergo intercrystalline cracking when tested above the equicohesive temperature,  $T_c$ . Cracking at the grain boundaries gives rise to stress intensification which affects the shape of the creep curve (see Fig. 2), the ductility, and the type of fracture.

### Summary and Conclusions

The results of the present investigation lead to the following conclusions:

1—A transition from low temperature to high temperature-type deformation in metals occurs under proper conditions of testing. The faster the

strain rate, the higher the temperature of transition or the temperature at which grain boundary flow begins.

2—The transition occurs at the point of change in slope of the straight lines which are obtained when the logarithm of the applied stress is plotted vs. the logarithm of the minimum creep rate or the logarithm of the rupture time.

3—At the transition the type of fracture of 2S and 3S aluminum changes from transcrystalline (ductile) to intercrystalline (brittle); the ductility decreases markedly. High purity aluminum does not show a marked change in the type of fracture.

4—The stress and the strain rate at which the transition occurs are related to the temperature as predicted by Mott's theory of grain boundary slip. The constants involved in Mott's equation are affected by the purity of the material.

5—A semilog plot of stress vs. minimum creep rate for high purity aluminum does not give straight lines if a wide range of creep rates is investigated. These results prove that the application of Eyring's theory of activated complex to the creep of metals, as suggested by Dushman et al.<sup>1</sup> and by Kauzmann,<sup>6</sup> is possible only within a narrow range of creep rates as a first approximation.

6—The temperature coefficient,  $Q$ , of creep rates at constant stress follows Boltzmann's equation:

$$\text{rate} = A e^{-Q/RT}$$

$Q$  decreases as the stress increases.

7—Data on primary creep of aluminum are in approximate agreement with Andrade's equation:

$$l = l_0 (1 + \beta t^{1/3}) e^{kt}$$

where  $\beta$ , the coefficient of primary creep, is a function of the applied stress.

### Acknowledgments

The authors wish to express their gratitude to the Aluminum Co. of America for their fine cooperation in furnishing a variety of material and the spectrographic analyses of the material supplied; and to the Bureau of Ships for support of this research program and permission to publish the results.

# Structure Observations of Aluminum Deformed in Creep At Elevated Temperatures

by Italo S. Servi and Nicholas J. Grant

THE creep and stress rupture properties of three grades of aluminum have been reported in a previous paper.<sup>1</sup> It was found that the stress coefficient of the creep rate and of the rupture time changes at the transition from low temperature-type to high temperature-type deformation. The transition corresponds to the equicohesion for grains and grain boundaries. In order to support the conclusions obtained from the examination of creep and stress rupture data, the deformed specimens were observed metallographically and a few special tests were conducted. The results of these qualitative observations are given in the present paper.

## Experimental Procedure and Results

Table I gives the types of aluminum specimens.<sup>1</sup>

The creep and stress rupture tests were conducted in simple tension at constant stress. Further details on the experimental techniques have been given.<sup>1</sup>

The test bars were electropolished in a perchloric-acetic mixture before testing and were observed after testing without any further preparation unless otherwise specified. Observations of specimen cross-sections were made after electrolytic polishing and etching. The samples were extended along a direction parallel to the longer side of the micrographs of Figs. 12 through 27.

The log-log plots of stress vs. minimum creep rate for the three grades of aluminum appear in Figs. 1 and 2. The reference numbers on each curve help relate the photographs to the conditions of testing, indicating where high temperature-type deformation and failure prevailed and where low temperature behavior prevailed.

**Deformation of Single Crystals at Very High Temperature:** An annealed, high purity aluminum specimen was slightly strained at one end and re-annealed. A large single crystal was formed at the strained end of the specimen during re-annealing; the other end remained polycrystalline (see Fig. 3). A stress of 50 psi was applied to the cold specimen to avoid loading at 1100°F. The temperature was then raised to 1100°F, kept at 1100°F for 3 hr, and lowered again to room temperature.

Fig. 4 shows the appearance of the specimen after testing. The single crystal deformed by gliding along parallel planes, while the polycrystalline part deformed mainly by grain boundary flow. Some grain growth occurred in the polycrystalline part.

Another high purity specimen, which had two large single crystals at the two ends and a polycrystalline zone in the middle portion, was tested at 1000°F under a stress of 100 psi. The appearance of the sample after test is shown in Fig. 5. Even

Fig. 1—Log-log plot of stress vs. minimum creep rate for high purity aluminum.

though considerable slip occurred in the single crystals, the fracture occurred in the weaker polycrystalline portion.

**Evidence of Grain Boundary Migration during Creep Testing:** A high purity, coarse grained specimen, which had a large crystal in the middle portion (see Fig. 6) was tested at 700°F under a constant stress of 175 psi for 30 hr. The appearance of the specimen after testing (Fig. 7) indicates that the large crystal deformed by gliding along parallel planes, while the rest of the specimen deformed mainly by grain boundary flow. Microscopic examination showed clear evidence of grain boundary flow and grain boundary migration, an example of

Table I. Types of Aluminum Specimens Used

| Material    | Al Purity, Pct | Grain Size, Mm                                | Designation       |
|-------------|----------------|-----------------------------------------------|-------------------|
| High purity | 99.995         | Single crystals or mixed grain size specimens | Special specimens |
| High purity | 99.995         | 1 to 3                                        | Coarse grained    |
| High purity | 99.995         | 0.05                                          | Fine grained      |
| 2S          | 99.3           | 0.02 to 0.03                                  |                   |
| 3S          | 98.2           | 0.05 to 0.4                                   |                   |

which is presented in Fig. 8. This micrograph can be interpreted as follows: 1—The original grain boundary was located at A. 2—Some grain boundary flow occurred (see displacement of the horizontal scratches.) 3—The grain boundary migrated to the position B.

When a boundary flows, a step is formed on the polished surface of the specimen; the grain boundary, therefore, is revealed as a black line. The apparent "thickness" of the grain boundary depends on the amount of displacement, as well as on the relative orientation of the grain boundary with respect to the polished surface.

A rather complex example of grain boundary flow

I. S. SERVI, formerly Research Assistant, Massachusetts Institute of Technology, is now Research Metallurgist, Union Carbide & Carbon Research Laboratories, Inc., Niagara Falls, N. Y., and N. J. GRANT, Member AIME, is Associate Professor, Dept. of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

Fig. 2—Log-log plot of stress vs. minimum creep rate for 2S and 3S aluminum.

and grain boundary migration is presented in the composite photograph of Fig. 9. Partial etching revealed the final location of the grain boundaries. A sketch of the micrograph of Fig. 9 is shown in Fig. 10, where the final position of the grain boundaries is indicated by a serrated line.

It seems logical to assume that the initial structure followed the grain boundaries marked A in Fig. 10 and that these boundaries migrated to the final positions, marked F, during the course of the creep test. A trace was left on the polished surface wherever grain boundary flow occurred. The examination of these traces suggests that the migration occurred according to the sequence A-B-C-D-E-F indicated in Fig. 10. However, some of the lines which are visible in Fig. 9 cannot be definitely identified as traces of a grain boundary. For instance,

the irregular lines marked C, which appear in the lower part of Fig. 10, can as well be interpreted as deformation bands.

The grain boundaries migrate away from their centers of curvature during creep testing at high temperatures. This phenomenon is of the same type as the grain boundary migration which occurs when cold-worked aluminum is annealed at a suitable temperature, as described by Beck and Sperry.<sup>2</sup>

Step-like grain boundaries were observed after creep testing in a few cases, as shown in Fig. 11. This unusual appearance is probably caused by the combination of flow and migration of two or more grain boundaries.

*Appearance of Deformed High Purity Aluminum as a Function of the Conditions of Testing:* When a coarse grained, high purity aluminum specimen is tested under low temperature conditions, the grain boundaries resist deformation better than the grains, and the fracture occurs along a more or less irregular edge. As the transition from low temperature to high temperature type of deformation is approached, the specimen deforms in a more uniform way and the fracture edge becomes smaller. Under high temperature conditions of testing, the grain boundaries flow, making the grain boundaries appear "thick." The specimen fails by drawing down to a point.

Possibly kinking or other complex types of deformation were active in all the specimens tested.

Fig. 9—High purity aluminum. Grain boundary flow and grain boundary migration during creep testing. Oblique illumination. X150.

Fig. 10—Sketch of the microstructure of Fig. 9. The direction of the grain boundary migration is indicated by the steps A to F.

However, the qualitative nature of the observations did not permit a clear differentiation between modes of deformation other than grain boundary flow and deformation in the grains. Therefore, all the deformation bands which were observed in the grains have been regarded as "slip bands."

The appearance of the deformed surface changes as a function of the conditions of testing. A few examples are presented in Figs. 12 through 16. Fig. 12 shows a typical "low-temperature" sample, i.e., the grain boundaries did not flow and the deformation occurred in the grains by localized glide along slip bands. Fig. 13 indicates the behavior of the material when the transition is approached. The grain boundaries are still inactive but the deformation of the grains is less localized. The appearance of a specimen tested at high temperature is shown in Fig. 14. There is evidence of grain boundary flow based on grain boundary "thickening," the slip spacing is larger, and a vague cellular appearance is noticed in some parts of the grains. Fig. 15 shows a part of a grain of a specimen tested at still higher temperature. The slip bands are noticeably wavy and a substructure is quite clear. Fig. 16 shows a less localized type of deformation of a high temperature specimen. Wavy slip bands and subgrains are visible. The appearance of fine grained specimens is shown in Figs. 17 through 19.

**Factors Affecting the Spacing of the Slip Bands—"Slipless" Flow:** According to Orowan<sup>8</sup> the minimum slip band spacing is inversely proportional to the applied shear stress according to the equation:

$$d = \frac{G a}{2 \tau} \quad [1]$$

where:  $d$  is the minimum slip spacing;  $G$ , the modulus of rigidity;  $a$ , the interatomic spacing; and  $\tau$ , the shear stress. Since:

$$G/\tau \cong E/\sigma \quad [2]$$

where:  $E$  is the modulus of elasticity, and  $\sigma$ , the tensile stress, in the case of aluminum:

$$d \cong 1/\sigma \quad [3]$$

when  $d$  is expressed in millimeters and  $\sigma$  in psi.

The average slip spacing observed in coarse grained, high purity aluminum, and the average dimension of the "cells," were plotted vs. the applied stress using log-log coordinates (Fig. 20). These data were obtained for samples strained from 15 to 40 pct. Measured values of cell size might vary by a factor of 2 from the averages reported.

The solid line of Fig. 20, which has slope  $-1$ , indicates that the average slip spacing is inversely proportional to the applied stress, at least as a first approximation. The average slip spacing is over 50 times larger than the minimum spacing predicted by Orowan's equation and is in closer agreement with the experimental values obtained by Yama-

guchi,<sup>4</sup> as indicated in Fig. 20. This fact can be at least partially justified as follows:

1—The experimental values of this work and of Yamaguchi<sup>4</sup> are the average slip spacings after moderate strain. Orowan's equation predicts the minimum spacing that is obtained after a sufficiently large amount of strain.

2—The experimental values refer to spacing as measured on the surface of the specimen. Orowan's equation predicts the true spacing normal to the slip planes.

The data plotted in Fig. 20 help explain the absence of slip bands (so-called "slipless flow"<sup>5</sup>) observed in some specimens. It was found that single crystals deformed by glide at all temperatures. On the other hand, at the higher temperatures and

slower strain rates, fine grained specimens deformed by slipless flow. Although this observation was reported long ago by Hanson and Wheeler,<sup>5</sup> it has never been suggested that there is an upper limit of grain size for "slipless flow" to occur. Observations of several specimens lead to the conclusion that this critical grain size is less than the average slip spacing measured on coarser grained specimens for the same value of stress.

For instance, Fig. 19 (at 1200 psi) shows no slip bands in the smaller grains, while one wavy slip band is present in the middle of the larger grains. From Fig. 20 the slip band spacing was calculated for the stress under which the sample of Fig. 19 was tested. At X150 the calculated slip band spacing is 7.5 mm. Fig. 19 indicates that 7.5 mm at X150 is

the order of magnitude of the size of the smaller grains and is approximately the distance between the slip bands and the nearest grain boundaries. The results indicate that grain boundaries have an inhibiting effect on the occurrence of slip bands.

In Fig. 15 there is observed a grain substructure which is delineated by the slip bands and boundaries roughly  $90^\circ$  to the slip bands. This substructure may, in fact, correspond to the cell structure of Wood et al.<sup>6</sup>

Fig. 20 further indicates that the average dimensions of the subgrains observed in several specimens are of the same order of magnitude as the average slip spacing. The dimensions and appearance of the subgrains suggest that they are probably related to the slip system.

*Appearance of Deformed 2S and 3S Al as a Function of the Conditions of Testing:* Similar results to those described for the high purity aluminum were obtained from the observations made on 2S and 3S aluminum. A notable difference in deformation between high purity aluminum and 2S or 3S aluminum is the absence or severe restriction of grain boundary migration in the latter case. For 2S or 3S aluminum, however, intercrystalline cracking is clearly shown in the specimens that were tested under high temperature conditions. Typical micrographs of the surface and of the longitudinal sections of several specimens are presented in Figs. 21 through 28. In Fig. 21 deformation occurred by glide in the grains. There are no grain boundary cracks (2S-low temperature). Fig. 22 shows evidence of grain boundary flow. No slip bands are apparent. The parallel markings in some grains are probably due to cracks in the oxide skin of the surface, perpendicular to direction of applied stress, (2S-high temperature). In Figs. 23 and 24, only Fig. 24, high temperature type behavior, shows intercrystalline cracking. Fig. 23, low temperature type behavior, shows grain elongation and no grain boundary cracks. The cracks in Fig. 24 are widened by the electrolytic polish. In Figs. 25 and 26 the slip is responsible for the def-

ormation of 3S aluminum at conditions of low temperature-type behavior. At a slower strain rate, still at 900°F, grain boundary flow and cracks are evident and slip is not evident. Fig. 27, a section of a 3S sample tested for low temperature-type behavior, shows that the grains stand a very large amount of strain without cracking at the grain boundaries at the high strain rates imposed. Near the fracture point recrystallization occurred, probably after failure. Fig. 28, the fracture of a 3S sample (high temperature behavior), is typically intercrystalline. The deformation of the grains is limited. As for Fig. 27, this test is also at 900°F but at much slower strain rates.

### Summary and Conclusions

1—The conditions of creep testing at which a

24

25

Figs. 24-26—25 aluminum specimens. X150.

Fig. 24—Longitudinal section at 900°F, 18.4 hr rupture time (point No. 12 of Fig. 2). Near fracture. Electrolytic polish and etch.

Fig. 25—At 900°F, 0.01 hr rupture time (point No. 13 of Fig. 2). R.A. is 23 pct.

Fig. 26—At 900°F, 58 hr rupture time (point No. 14 of Fig. 2). R.A. is 5 pct.

change in slope occurs in the log-log plot of stress vs. minimum creep rate or stress vs. rupture time correspond to the beginning of grain boundary flow (equicohesion), but are not directly related to the absence of slip bands.

2—Grain boundary migration occurs in high purity aluminum tested under high temperature conditions. The grain boundaries move away from their center of curvature, as in the case of annealing after cold working.

3—As a first approximation, for specimens deformed 15 to 40 pct, the spacing of the slip bands observed is inversely proportional to the applied stress.

4—Absence of slip bands ("slipless flow") occurs

27

28

Figs. 27-28—3S aluminum, longitudinal section at 900°F.

Fig. 27—0.01 hr rupture time (point No. 13 of Fig. 2). Fracture point. Electrolytic polish and etch. X50.

when the grain size is smaller than the average slip spacing observed in a coarser grained specimen tested under the same applied stress.

5—The deformation of aluminum is less localized the higher the temperature, or the slower the strain rate. Subgrains were observed in some specimens tested at high temperature. The dimensions of these subgrains are of the same order of magnitude as the average slip spacing.

6—The dimension, shape and regularity of the subgrains observed in high purity aluminum suggest that the subgrains are related to the slip process or to other less known deformation processes such as kinking. The subgrain formation appears to be the effect, not the cause, of plastic deformation.

# Solubility Relationships in Some of the Ternary Systems Of Refractory Monocarbides

by John T. Norton and A. L. Mowry

Isothermal sections of the pseudo-ternary carbide systems TiC-VC-ZrC, TaC-VC-ZrC, and NbC-VC-ZrC have been examined. The sections contain an inverted U shaped two-phase field whose maximum extent is 77 molecular pct for TiC, 64 pct for TaC, and 51 pct for NbC. Isoparametric lines were determined which show the curvature of the single-phase field and the direction of tie lines in the two-phase field. It was not possible to show any relationship between atom size and the extent of the two-phase field.

PREVIOUS work<sup>1</sup> on the solubility relationship of several pairs of refractory cubic monocarbides from the group TiC, ZrC, VC, NbC, and TaC has shown that, with the exception of the system VC-ZrC, they all form continuous series of solid solutions. It was demonstrated that the limited solubility in the case of VC-ZrC system was primarily a question of the size factor, the size difference between vanadium and zirconium being greater than the limiting value of about 15 pct.

It is interesting to consider the results of combining these isomorphous carbides in groups of three and to determine the isothermal section of the pseudo-ternary diagram at, for instance, 2000°C, a temperature that will assure an equilibrium structure in a reasonable length of time.

In the ternary systems where the three pairs form complete solid solution series, it is probable that the isothermal ternary section would be a single-

Table I. Metal Atom Diameter Based on Interatomic Distance in Pure Carbide

| Metal | Diameter, A |
|-------|-------------|
| V     | 2.66        |
| Ti    | 2.82        |
| Ta    | 2.95        |
| Nb    | 2.96        |
| Zr    | 3.18        |

phase field, although this is not necessarily the case. However, if one pair of carbides has a very limited solubility, then there must be a two-phase field of some extent, and it is the purpose of the present work to examine the extension of this field and to determine if it can be related to the nature of the third carbide. This condition is fulfilled if the VC-ZrC pair, which has only limited solubility, is combined with TiC, TaC, or NbC.

The relative sizes of the metal atoms undoubtedly play a role in the extent of the single-phase field, and the values obtained from the pure carbides, assuming close-packing between metal and carbon atoms and a carbon atom diameter of 1.54A, are

<sup>1</sup> J. T. Norton and A. L. Mowry: *Trans. AIME* (1949) 185, p. 133; *JOURNAL OF METALS* (February 1949).

given in Table I. From these values it would be expected that NbC and TaC would be closely alike in behavior, while TiC would be somewhat different. It is not possible however, to predict whether the single-phase field would be enlarged or reduced.

#### Specimen Preparation

The alloys were prepared by vacuum sintering a mixture of the three separate carbides.

The commercial carbides used were from the same sources as described previously.<sup>1</sup> They were somewhat deficient in combined carbon. Consequently the carbides were weighed out in the quantities required and sufficient additions made of a pure carbon black to give the desired proportions. Some preliminary runs were made that gave indications of the extent of the two-phase field. Then the final compositions were prepared, not only to define the boundary, but also to give some information on the two-phase field. About 30 compositions were used for each ternary system.

The lots were of 10 g each and were mixed in the small laboratory ball mill for 4 hr, using benzene as a dispersing agent. About 0.5 pct of paraffin was added to assist in pressing. After ball milling, the powders were dried and pressed into small cylindrical slugs.

The sintering was carried out in a resistance-heated vacuum furnace with the specimens in graphite containers. The heating time was 12 hr at 2000°C to insure that equilibrium was reached in the specimens. The furnace construction was such that very rapid cooling was obtained as soon as the power was shut off. In the first minute, the temperature dropped approximately 500°C and it is believed that this is sufficiently rapid cooling to retain the structure, which is stable at the sintering temperature. The temperature was controlled manually and was maintained to within  $\pm 20^\circ\text{C}$ .

The slugs sintered into strong and fairly dense

bodies. They were of a clean gray metallic appearance except for the specimens high in TaC, which had a yellowish cast. With one exception, the specimens gave sharp X-ray diffraction lines, indicating that the phases in the alloys were of uniform composition. The exception was a group of three specimens in the NbC-VC-ZrC system close to the boundary where the two phases present were not very different in lattice parameter and seemed to be much slower in reaching equilibrium.

#### X-ray Measurements

Since the purpose of the investigation was to locate the boundary of the two-phase field in the isothermal section, the greater part of the X-ray examination was done with the aid of the Norelco Recording X-ray spectrometer. Experiments on mixed samples of known composition showed that about 2 molecular pct of the vanadium-rich phase would appear as distinct lines in the presence of 98 pct of the zirconium-rich phase. This is the most difficult case and proves that the method is sufficiently sensitive for the purpose. Parameter measurements of the phases were also made from the Norelco records with sufficient accuracy to determine the important features of the diagrams. Where more precision was desired, a Phragmen focusing camera, covering the angular range of Bragg angles from  $60^\circ$  to  $87^\circ$  was employed. Copper  $K_\alpha$  radiation was used throughout the experiments.

The position of points on the phase boundary was determined by noting whether the pattern contained one or two phases. In the region of the boundary, the specimen compositions were quite close together and the X-ray method gave values which probably are within  $\pm 2$  molecular pct. Attempts were made to use a modification of the disappearing phase technique by measuring the ratio of the X-ray line intensities and extrapolating to zero, but the results were no more consistent or precise than the simple observation of the existence of one or two phases

Fig. 2—System TiC-VC-ZrC showing the isoparametric lines. The figures are the lattice parameters of the phases in Angstrom units.

when the compositions were close enough together. At the top of the two-phase field, it is not a case of one phase disappearing but rather two sets of lines merging into one.

If the direction of the tie lines in the two-phase field had been known, and series of alloys prepared lying on these lines, then the precise analytical method of the disappearing phase technique could be applied, but these tie lines, of course, could not be known in advance.

In order to show the distortion of the parametric surface as the single-phase field approaches the two-phase boundary and to find the direction of the tie lines in the two-phase field, the lattice parameters of all of the alloys were measured. The experimental values showed some degree of scatter, and the method used was to plot the measured values along some composition lines of the diagram and draw a smooth curve through the points. The values used in plotting the isoparametric lines were then taken from these smooth curves. The results obtained in this way appear very consistent.

### Results

The results of the phase boundary determinations are shown in Fig. 1 where the curves for the three systems are plotted on a single diagram. The curves are similar in shape and fairly symmetrical. The upper nose of the curve extends to 77 molecular pct in the case of TiC, to 64 pct for TaC, and 51 pct for NbC. On the basis of atom size there appears to be no obvious explanation for the relative positions of these three curves.

The isoparametric lines for the three systems are shown in Figs. 2, 3, and 4. They indicate the fact that the parametric surface of the single-phase region is not plane and that considerable distortion occurs. Compared with the plane surface to be expected from the simple rule of mixtures, the true surface is elevated above this plane as it approaches the boundary of the two-phase field. The greatest distortion is shown in the TiC-VC-ZrC system, especially on the low VC side. In this narrow strip,

Fig. 3—System NbC-VC-ZrC showing the isoparametric lines. The figures are the lattice parameters of the phases in Angstrom units.

Fig. 4—System TaC-VC-ZrC showing the isoparametric lines. The figures are the lattice parameters of the phases in Angstrom units.

the surface is actually rising when the VC content is increasing, while on the rule of mixture basis it would be falling.

The isoparametric lines in the two-phase fields are actually tie lines, since each point on the phase boundary corresponds to a definite lattice constant. Since the lines are plotted for specific values of the lattice constant, it would not be expected that the lines for the two phases would coincide, but obviously tie lines cannot cross and their trend should be such as to approach the horizontal at the base, that is, the VC-ZrC binary. The experimental results show this trend in the slope in a very definite fashion. In the systems containing TaC and NbC, the slope is downward toward the VC corner while in the TiC system, the slope is toward the ZrC corner.

The positions of the tie lines on the pseudo-ternary diagrams are important because they indicate the directions of the reactions occurring and the phases that will exist together in equilibrium when sintered bodies are made with these carbide combinations.

Unfortunately it does not appear possible to relate the curvature of the single-phase parametric surface or the direction of the tie lines to the properties of the metal atoms involved. In this respect tantalum and niobium resemble one another in behavior more than either resembles titanium. But there is no clear relationship to either atom size or chemical nature. The marked departure of the lattice constants from conditions to be expected from the rule of mixtures suggests that an examination of some of the pseudo ternaries where the three carbides form completely soluble binaries would be of interest. There is a real possibility that a two-phase field would be found.

# High Temperature Oxidation of Copper-Palladium and Copper-Platinum Alloys

by D. E. Thomas

Oxidation rate constants were determined for Cu-Pd and Cu-Pt alloys as a function of alloy composition and temperature. Reaction products were identified. Relationship between oxidation rate constants and diffusion constants in the reaction zones is discussed.

THE mechanism of oxidation of alloys is considerably more complex and not so well understood as that of pure metals. The oxidation of a one-phase binary alloy of which one component is a noble metal should logically be the simplest case of alloy oxidation, for in this case one is concerned presumably only with the oxidation of the base metal and the diffusion process by which it reaches the reaction site. This had led a number of investigators to study such systems. Probably the earliest work was that of Tammann and Rienäcker<sup>1</sup> on the tarnishing of Cu-Au alloys at temperatures up to 300°C. These alloys oxidize according to the logarithmic law, that is, the film thickness is proportional to the logarithm of the time. The rate of film formation was found to decrease with increasing gold content. Raub and Engel<sup>2</sup> investigated the oxidation of Au-Cu, Cu-Pd, Au-Ag-Cu, Au-Pd-Cu, and Ag-Pd-Cu alloys at 750°C in air. These alloy systems form a continuous series of solid solutions at the temperature of oxidation with the exception of those containing silver.

Au-Cu alloys oxidize parabolically, the rate constant decreasing slowly with increasing gold content up to about 15 atomic pct\* Au, and more rapidly thereafter. An alloy with 14 pct Cu forms only a very thin layer of CuO on the surface and probably also a subscale.† Alloys containing more than 14 pct Cu have scales consisting of CuO and subscales of Cu<sub>2</sub>O embedded in nearly pure gold. The Cu-Pd

alloys obey the parabolic law except for slight deviations for alloys containing 53 and 84 pct Cu. The overall oxidation rate decreases rather smoothly with increasing palladium content. A scale consisting of a thin layer of CuO and a thick layer of Cu<sub>2</sub>O and a subscale of Cu<sub>2</sub>O embedded in nearly pure palladium was observed for alloys containing 84, 53, and 30 pct Cu. An alloy with 19 pct Cu formed only a subscale of CuO embedded in nearly pure palladium, and an 8 pct Cu alloy formed only a thin film which was presumed to be PdO. The ternary alloys considered by Raub and Engel oxidized in much the same way as did the binaries.

Wagner and Grunewald<sup>3</sup> found that Ni-Au alloys, oxidized at 900°C in oxygen, formed a scale of NiO and a subscale containing NiO and gold. The overall oxidation rate increases with increasing gold content, passes through a maximum and then decreases to zero for pure gold. The fact that gold increases the oxidation rate was attributed to "pores" in the scale.

Kubaschewski<sup>4</sup> investigated the air oxidation of alloys of platinum or gold with up to 10 pct Cu or Ni at temperatures in the range 300° to 1550°C. Parabolic behavior was noted for all alloys except Au-Ni, with rates decreasing in the order Au-Cu, Au-Ni, Pt-Ni, Pt-Cu. The diffusion coefficients for the latter three systems are known, and they decrease in the same order. However, activation energies for the oxidation of these alloys do not agree with the activation energies for diffusion in the respective alloy systems.

Kubaschewski and Goldbeck<sup>5</sup> investigated the oxidation of Ni-Pt alloys in air at temperatures of 600°

D. E. THOMAS, Junior Member AIME, formerly a graduate student at Carnegie Institute of Technology, is now with Westinghouse Electric Corp., Atomic Power Division, Pittsburgh.

Discussion on this paper, TP 3137E, may be sent, 2 copies, to AIME by Dec. 1, 1951. Manuscript, April 12, 1951. Detroit Meeting, October 1951.

This paper represents part of a thesis by D. E. Thomas submitted in partial fulfillment of the requirements for the degree of Doctor of Science to the Graduate Committee of the Carnegie Institute of Technology, Pittsburgh, June 1950.

\* All subsequent percentage compositions are given in terms of atomic percent.

† The term subscale or zone of internal oxidation here refers to a reaction zone containing two phases, one of which is an oxide, the other metal, situated between the innermost external scale layer and the unoxidized metal.

to 1350°C. As was pointed out in a discussion of their paper, the correct interpretation of their data is that the overall rate constant decreases gradually with increasing platinum content. Their data are not sufficiently precise to test the validity of Wagner's theory of the oxidation of noble metal-base metal alloys.<sup>11</sup>

A study of these publications shows that a subscale is formed under the scale of the base metal, and that the addition of a noble metal to a base metal never results in a disproportionate improvement in the oxidation resistance of the alloy.

Heretofore only overall weight gains have been employed to describe the extent of oxidation, and no quantitative measurements were made on the rates of growth of the individual reaction layers. The role of diffusion in the metal phase and in the oxide phase has not been quantitatively demonstrated for the oxidation of alloys containing noble metals. The present work was undertaken to clarify these points.

### Experimental Procedure

Alloy samples were made from 0.040 to 0.050 in. sheet which was rolled from small vacuum induction melted ingots. Materials used were special carbon-reduced copper obtained from Westinghouse Electric Corp. and c.p. grades of palladium and platinum. The alloy compositions used are listed in Tables I and V. Prior to oxidation, the surfaces of each specimen were polished metallographically, and degreased in alcohol or acetone. Oxidation was carried out in vertical tube furnaces equipped with gasketed pyrex tubes mounted above the furnaces in such a way that the specimen could be lowered from the pyrex tube into the furnace, or raised from the furnace into the pyrex tube, without admitting air to the system. Oxygen was admitted to the system at a pressure slightly in excess of atmospheric pressure through suitable tubulation. Specimens were suspended in the system by means of a platinum wire or a quartz fiber. The specimens were oxidized for various times at temperatures of 850°, 925°, and 1000°C. The alloy systems investigated form a continuous series of solid solutions at these temperatures. The specimens were weighed before and after oxidation. After oxidation the samples were electroplated with a thick layer of copper and sectioned perpendicular to the surface. The cut surface was then polished metallographically and the scale and subscale thicknesses measured from a negative metallographic plate, the electroplated copper serving to delineate sharply the outer scale surface. Because of irregularities in the scale and subscale thickness, it was necessary to compute averages from measurements obtained at regular intervals determined by placing a grid of 10 or 15 lines under the negative. Thus the overall weight gain as well as the scale and subscale thickness was determined.

The scale structure was determined by a combination of optical and X-ray diffraction observations. Cuprous oxide, viewed under the microscope by reflected light, appears blue-gray, and cupric oxide also appears blue-gray, but with a slight pink tinge. Under polarized dark field illumination cuprous oxide appears red and cupric oxide appears nearly black. This permitted the identification of the scale structure for most of the alloys. However, it was found that with increasing palladium content cuprous oxide appeared progressively darker under polarized light, so that it was sometimes difficult to discriminate between cuprous and cupric oxide visually.

Accordingly, samples containing 50 to 85 pct Pd and oxidized at temperatures of 850° and 1000°C were scraped clean of their oxide in order to obtain a powder sample of the scale for analysis by X-ray diffraction using standard techniques. This method of removing the scale yielded a sample which included the scale and also a part of the subscale. Such samples were exposed in a cylindrical powder camera using cobalt radiation with an iron filter. The identity of lines on the film was established by direct comparison with standards run in the same camera. The information so obtained permitted a more definitive visual re-examination of the specimens under the microscope, so that it was possible to identify the oxides of the scale and subscale.

In order to determine the composition of the metal at the scale/subscale interface, the scale was removed in a 10 pct KCN solution from 35 pct Pd alloy samples oxidized at 850° and 1000°C for various times. The descaled samples as well as standard samples were placed in a back-reflection Laue camera, with the scale/subscale interface perpendicular to the incident beam. The palladium content at the scale/subscale interface was then determined from the precision lattice parameters so determined.

The alloy composition in equilibrium with cuprous oxide was determined for the Cu-Pd system. An alloy containing 8.45 pct Pd was selected because the subscale in a fully oxidized specimen of this composition consists of particles of Pd-rich alloy embedded in cuprous oxide, thus making possible a clean separation of phases. Samples of this alloy were oxidized in oxygen at temperatures of 850°, 925°, and 1000°C for times equal to two or three times those required to oxidize the samples to the core, but not long enough to cause an appreciable amount of cupric oxide to grow. Each specimen was powdered and the oxide dissolved in a solution of KCN in glycerine, leaving the Pd-rich particles as a residue. Chemical analyses were then made on this residue.

In order to find out whether a subscale could be produced in Cu-Pd alloys in the absence of an external scale, specimens containing 8.45 and 37.5 pct Pd were packed in a closed pipe with a mixture of copper and cuprous oxide powders and heated for 18 hr at 860°C.

Qualitative chemical analyses were made on scales flaked or abraded from several alloys in order to determine the palladium content of the oxide. One Ni-15 pct Pt alloy was oxidized under the same conditions described above. It was desired only to discover whether a subscale would be formed.

### Scale Structure

*Cu-Pd Alloys:* All of the Cu-Pd alloys investigated formed a scale and a subscale upon oxidation,

Table I. Scale Structures Formed on Cu-Pd Alloys

| Pd Content, Atomic Pct                   | Temperature of Oxidation, °C | Sub-scale              | Scale (Outer/Inner)            |

|                                          | 850 to 1000                  | α + PdO                | PdO                            |
|                                          | 850 to 1000                  | ?                      | PdO film                       |

\* α designates the palladium-rich solid solution.

Fig. 1—Cu-Pd alloys oxidized in  $O_2$  at  $925^\circ C$  for 2 hr. Atomic pct Pd indicated.

with the exception of the 95.14 pct Pd alloy, which formed only a thin film of oxide on the surface. No subscale is formed in pure copper. The scale and subscale structures as revealed by visual and X-ray diffraction methods are shown in Table I. It will be noted that the alloys containing less than 50 pct Pd form a subscale of  $\alpha + Cu_2O$  and a  $Cu_2O$  scale layer with a very thin outer layer of  $CuO$ . The scale formed on the 51.45 pct Pd alloy oxidized at  $1000^\circ C$ , however, is about  $\frac{1}{4} CuO$  and  $\frac{3}{4} Cu_2O$ . No  $Cu_2O$  is found on this alloy when oxidized at  $850^\circ$  or  $925^\circ C$ . At 69.92 pct Pd,  $CuO$  appears in the subscale and  $PdO$  appears in the scale. Whether  $PdO$  appears as a distinct layer or as a mixture with  $CuO$  in the scale formed on this alloy could not be determined. Only  $PdO$  was found in the scale and subscale of the 86.5 and 95.14 pct alloys.

It was noted in the X-ray diffraction patterns of the scales removed from the alloys that the  $Cu_2O$  lines and  $CuO$  lines were shifted slightly in the direction corresponding to increasing lattice para-

meter relative to the lines obtained on the pure substances.

Alloy samples containing 8.45 and 37.5 pct Pd heated in a closed container with copper and cuprous oxide powders did not form a zone of internal oxidation.

Chemical analysis of the scale from a 5 pct Pd alloy oxidized at  $925^\circ C$  indicated  $<0.001$  pct Pd, and that removed from a 37.5 pct Pd alloy was found to contain a trace of palladium. Further evidence of palladium in solid solution in the cuprous oxide was afforded by the fact that the characteristic red color of cuprous oxide when viewed under polarized light became darker with increasing palladium content of the alloy. This effect was also observed in the Cu-Pt alloys, but was less pronounced.

The Pd-rich particles which had been separated from specimens oxidized for time periods in excess of those required for complete oxidation to  $Cu_2O$  were found to have the compositions listed in Table II. The compositions given are those in equilibrium with  $Cu_2O$  and oxygen at the indicated temperature.

The composition of the alloy phase in the subscale at the scale/subscale interface as measured by X-ray determination of lattice parameters is shown in Table III. Because the metal phase is saturated with

Initial Alloy Composition: 37.5 Pct Pd

| Temperature of Oxidation, $^\circ C$ | Time of Oxidation, Hr | Interface Composition, Pct Pd |
|--------------------------------------|-----------------------|-------------------------------|
| 850                                  | 2                     | 64.6                          |
| 850                                  | 4.8                   | 68.8                          |
| 1000                                 | 2                     | 68.5                          |
| 1000                                 | 8                     | 73.3                          |

Fig. 4 (left)—Cu-Pt alloys oxidized in  $O_2$  at  $925^\circ C$  for 2 hr. Atomic pct Pt indicated. X200.

Fig. 5 (right)—Ni-15 atomic pct Pt alloy oxidized in  $O_2$ . X200.

oxygen the values shown are probably higher than the true values. It will be noted that the composition of the alloy phase of the subscale at the subscale/scale interface appears to be dependent upon time. These data cannot be considered conclusive, however, since the depth of penetration of X-rays into the subscale layer yields an average composition of the concentration gradient to this depth. Since the gradient is steeper for short oxidation times, a smaller apparent palladium content would be anticipated.

**Cu-Pt Alloys:** The Cu-Pt alloys investigated (0 to 25 pct Pt) all exhibited a scale of  $Cu_2O$  with a very thin layer of  $CuO$  on the outer side. A subscale was also observed in all samples and consisted of  $Cu_2O$  distributed in a matrix of Pt-rich alloy. It was observed that, in contrast to the Cu-Pd alloys, the  $Cu_2O$  in the scale and subscale darkened only slightly with increasing concentration of noble metal in the alloy when viewed under polarized light.

**Ni-15 Pct Pt Alloy:** A scale of  $NiO$  was observed to form on the Ni-15 pct Pt alloy. There was also formed a subscale consisting of  $NiO$  particles embedded in Pt-rich alloy. This fact has not been re-

ported in previous work on the oxidation of Ni-Pt alloys.<sup>5</sup>

#### Morphology of Scale and Subscale

**Cu-Pd Alloys:** As will be seen subsequently, the external scale thickness increases with increasing temperature and decreases with increasing noble metal content for a given time of oxidation. The extent of the subscale increases with temperature and passes through a maximum as the palladium content increases. The micrographs in Fig. 1 show the structures resulting from oxidation at  $925^\circ C$  for 2 hr as a function of palladium content.

**Subscale:** As may be seen in Fig. 1, the particle size of the subscale oxide decreases from massive in the Cu-rich alloys to very fine in the Pd-rich alloys. The particle size of the subscale oxide increases with the temperature of oxidation. Within a given subscale, larger particles are found near the subscale/alloy interface.

The metal phase of the subscale is continuous in all of the alloys except the 5.19 pct Pd alloy and possibly the 15.13 pct Pd alloy. The relative amount of metal phase in the subscale increases with increasing palladium content, increasing temperature, and distance from the scale/subscale interface.

Table IV. Rate Constants for the Oxidation of Cu-Pd Alloys

| Composition, Atomic Pct | $T$ , $^\circ C$ | Oxygen pressure: 1 atm          |                                    |                                                 |
|-------------------------|------------------|---------------------------------|------------------------------------|-------------------------------------------------|

Fig. 6—Square of the scale and subscale thickness vs. time for Cu-15.13 atomic pct Pd alloy oxidized in  $O_2$ .

Fig. 7—Temperature dependence of the parabolic rate constant based on scale thickness for the oxidation of Cu-Pd alloys. Atomic pct Pd indicated.

There is a definite tendency for the subscale oxide to precipitate at grain boundaries, becoming more pronounced with increasing palladium content. The grain boundary effect is typified in Fig. 2. The grain boundaries near the scale/subscale interface are not usually as well defined by oxide particles as those near the subscale/alloy interface. This suggests that there is a considerable amount of rearrangement of the oxide particles which formed early.

It will be noted in Fig. 2 that grain boundaries nearer the scale/subscale interface contain more

Fig. 8—Temperature dependence of the parabolic rate constant for subscale thickness for Cu-Pd alloys. Atomic pct Pd indicated.

oxide particles than those near the subscale/alloy interface, suggesting that the formation of grain boundary oxide results from the formation of a few nuclei which grow in the grain boundary until they impinge.

There is a tendency for plate-like oxide particles to be thicker when oriented parallel to the specimen surface. This is most pronounced in the Pd-rich alloys.

**Scale:** The grain size of the external scale is in general of the same order of magnitude as the scale thickness. No systematic measurements were made, however. When a CuO layer of appreciable thick-

Fig. 9—Parabolic rate constants  $K_E$  and  $K_S$  as a function of alloy composition. Cu-Pd alloys oxidized in  $O_2$ , 1 atm pressure.

ness is formed, the surface of the oxide takes on a rough grained appearance.

An increasing number of spherical voids in the  $Cu_2O$  scale was observed with increasing palladium content and with increasing temperature. The number of voids varied from a few to 5 or 6 per field at 500X. The maximum number was found in the 37.5 pct Pd alloy. Above this palladium content no voids were found. Fig. 3 shows voids in the scale formed on a 37.5 pct Pd alloy.

**Cu-Pt Alloys:** The microstructures shown in Fig. 4 for the oxidation of Cu-Pt alloys at 925°C for 2 hr are typical of those found at the other temperatures.

The same tendencies noted for the particle size of the subscale oxide in the Cu-Pd alloys were noted for the Cu-Pt alloys. In general the particle size was finer in the subscale of the Cu-Pt alloys. The metal phase is continuous in the subscale of all the Cu-Pt alloys investigated, and the tendency for grain boundary precipitation is more pronounced in the Cu-Pt system than in the Cu-Pd system at comparable noble metal concentration.

The morphological features of the scales formed

on Cu-Pt alloys are similar to those formed on Cu-Pd alloys.

**Ni-15 Pct Pt Alloy:** The scale and subscale were quite irregular in thickness. The particle size of the NiO in the subscale was relatively fine and increased with increasing temperature of oxidation. Fig. 5 shows that there is no tendency toward grain boundary precipitation in the subscale and that the metal phase is continuous.

### Kinetics

The parabolic law was found to describe the oxidation of most of the alloys investigated. Since the thickness of the scale and subscale as well as the

Fig. 10—Temperature dependence of the parabolic rate constant based on scale thickness for the oxidation of Cu-Pt alloys. Atomic pct Pt indicated.

overall weight gain was observed, the data were treated using the following equations:

$$\Delta m^2 = K_m t \quad [1]$$

$$E^2 = K_E t \quad [2]$$

$$S^2 = K_S t \quad [3]$$

where  $\Delta m$  is the weight gain in mg per  $\text{cm}^2$ ;  $E$ , the external scale thickness in cm;  $S$ , the subscale thickness in cm;  $t$ , the time in sec; and  $K$ , the respective parabolic rate constant.

**Cu-Pd Alloys:** Typical curves showing the square of the external scale thickness and the square of the subscale thickness plotted against time are shown in Fig. 6. From such curves the parabolic rate constants were calculated for the scale, the subscale, and the gross weight gain. These are given in Table IV and need no comment other than to point out the anomalous behavior of the 86.5 pct Pd alloy oxidized at 1000°C. It was found that some specimens of this alloy formed a film while others formed a scale. No correlation of this behavior could be made with minor variations in the experimental conditions.

Fig. 11—Temperature dependence of the parabolic rate constant for subscale thickness for Cu-Pt alloys. Atomic pct Pt indicated.

The temperature dependence of the rate constants,  $K_E$  and  $K_S$ , is shown in Figs. 7 and 8 wherein the logarithms of the respective rate constants have been plotted against the reciprocal of the absolute temperature. It is to be noted that a straight line results only for  $K_E$  for pure copper and for the 69.9 pct Pd alloy. Thus in most cases the activation energy increases with increasing temperature. The temperature dependence of  $K_m$  is similar to that for  $K_E$ .

Fig. 12—Parabolic rate constants  $K_E$  and  $K_S$  as functions of alloy composition. Cu-Pt alloys oxidized in  $\text{O}_2$ , 1 atm pressure.  $K_E$  for Cu-Pd alloys is shown for comparison.

Fig. 13—Temperature dependence of the parabolic rate constants  $K_m$ ,  $K_E$ , and  $K_S$  for the oxidation of Ni-15 atomic pct Pt alloys.

The dependence of  $K_E$  and  $K_S$  upon the palladium content is illustrated in Fig. 9, in which the rate constants are plotted on a log scale for convenience. It is seen that  $\log K_E$  decreases linearly with increasing palladium content up to about 25 pct Pd. Subsequently,  $\log K_E$  begins to drop off more rapidly until there is only CuO in the external scale, at which juncture an inflection occurs (40 to 50 pct Pd). With further increase in palladium content, the rate at which  $\log K_E$  drops off appears to decrease until PdO appears as the external scale at a palladium content between 70 and 85 pct. With the onset of the PdO scale,  $\log K_E$  undergoes a rather

sharp decrease. The behavior is essentially the same at the three temperatures investigated.

The shape of the curve of  $\log K_S$  vs. palladium content varies considerably with temperature, with maxima occurring at 50 pct Pd at 1000°C, 15 to 20 pct Pd at 925°C, and 5 pct Pd at 850°C. The maxima occur in the concentration range in which the subscale oxide is  $\text{Cu}_2\text{O}$  and the external scale is largely  $\text{Cu}_2\text{O}$ .

**Cu-Pt Alloys:** The rate constants,  $K_E$ ,  $K_S$ , and  $K_m$ , for the Cu-Pt alloys are listed in Table V. In some instances deviations from parabolic behavior were found after 6 hr. In such cases the rate constant was calculated from the data up to 6 hr oxidation time.

The temperature dependence of  $K_E$  and  $K_S$  is shown in Figs. 10 and 11, respectively. The activation energy for  $K_E$  and  $K_S$  is seen to increase with temperature. A similar temperature dependence for  $K_m$  was found.

The effect of platinum content upon  $K_E$  and  $K_S$  is shown in Fig. 12.  $\log K_E$  decreases with increasing palladium content in a complex way. The corresponding curves for Cu-Pd alloys are also indicated in Fig. 11, and it is seen that  $K_E$  is greater for the Cu-Pd alloys than for Cu-Pt alloys at the same temperature and composition.

The  $\log K_S$  vs. platinum curve passes through a broad maximum at about 14 pct Pt, which does not depend upon the temperature.

**Ni-15 Pct Pt Alloy:** The data for weight gain, scale thickness, and subscale thickness showed a great deal of scatter. It was therefore necessary to assume parabolic behavior and to calculate the rate constants giving the best fit.  $K_E$ ,  $K_S$ , and  $K_m$  are listed in Table V. The  $K_E$  values for pure nickel in Table V are calculated from the  $K_m$  values given by Kubaschewski and Goldbeck.<sup>6</sup> In view of the scattering of the present data and that of the Kubaschewski and Goldbeck data, no statement can be made concerning the effect of platinum on the rate constants.

The effect of temperature upon  $K_E$  and  $K_S$  is shown in Fig. 13. The activation energy for  $K_E$  is 29,900 cal per mol and for  $K_S$  is 66,400 cal per mol.

## Discussion of Results

**Scale Structure:** It is of interest to consider the several sequences of phases observed for the oxidation of Cu-Pd alloys in relation to the ternary equilibrium diagram involving copper, palladium, and oxygen. Such a treatment for the internal oxidation of the  $\alpha$  solid solutions of copper has been discussed in detail by Rhines.<sup>7</sup> Fig. 14 is a schematic representation of an isothermal section of the Cu-Pd-O system in which the extent of solid solubility has been exaggerated for clarity. One and two-phase fields in the diagram correspond to one and two-phase layers in the oxidized specimen, while three-phase fields in the diagram correspond to interfaces in the specimen. Reference to Table I shows that five distinct modes of oxidation were observed for the Cu-Pd alloys. The locus of compositions is shown schematically in Fig. 14 for each of these modes. Consider case A, which represents the alloys containing up to 37.5 pct Pd. The initial copper concentration is  $C_0$ , and, as one passes toward the outside of the specimen, the copper concentration decreases until a value  $C_1$  is reached at the alloy/subscale interface. Upon traversing the subscale region, the locus of average compositions in the subscale is indicated by the line connecting  $C_1$  and  $\text{Cu}_2\text{O}$ .

Fig. 14—Isothermal section of the Cu-Pd-O equilibrium diagram. Distorted scale.

The composition of alloy and oxide at a given position in the subscale is given by the ends of the tie line passing through the average composition at this position. Thus, at the subscale/scale interface the alloy composition is given by  $C_2$  and the oxide composition by  $C_3$ . Upon passing through the  $\text{Cu}_2\text{O}$  scale the copper concentration will decrease from  $C_3$  to  $C_4$ . From  $C_4$  the locus of compositions passes through the  $\text{Cu}_2\text{O} + \text{CuO}$  field. This structure, however, was not found, which may mean simply that this reaction layer was too thin to resolve. The relationship of the above composition loci to the kinetics involved may be seen by comparison with Fig. 18. The above reasoning may be applied to the other modes of oxidation indicated by B, C, D, and E, in Fig. 14. Mode A is to be considered typical also for the Cu-Pt alloys studied.

It was shown that palladium or platinum is taken into solid solution in cuprous oxide. This fact appears to be the crux of the subscale question. The effect of palladium or platinum addition to cuprous oxide is to increase the partial pressure of oxygen in equilibrium with the oxide, in view of the fact that alloys packed in  $\text{Cu}_2\text{O}$  powder do not form subscales while the same alloys do form a subscale under a  $\text{Cu}_2\text{O}$  scale containing a small amount of noble metal. It is seen in Fig. 15 that at the scale/subscale interface the palladium (or platinum) content in the metal phase is higher than at any other place. Hence the oxide in contact with this metal phase must have more palladium (or platinum) in solid solution, and consequently a higher partial pressure of oxygen,  $P_{\text{O}_2}^s$ . However, at the alloy/subscale interface the palladium concentration is less than at the scale/subscale interface, and the pressure of oxygen at the alloy/subscale interface is thus smaller than  $P_{\text{O}_2}^s$ . The difference,  $P_{\text{O}_2}^s - P_{\text{O}_2}^i$ , represents the driving force for diffusion of oxygen across the subscale. The composition of the oxide in the subscale is a function of the distance from the scale/subscale interface, being higher in palladium at the scale/subscale interface. These relationships can be seen by considering the tie lines in the  $\alpha + \text{Cu}_2\text{O}$  field in Fig. 14. It is apparent then that if  $\text{Cu}_2\text{O}$  could not take palladium into solution, there could be no gradient of oxygen pressure across the two-phase field, hence no subscale. This may be general for the oxidation of binary alloys with one noble component.

**Morphology:** The formation of the subscale may properly be thought of as a nucleation and growth process taking place isothermally under the influence of diffusion currents. The number of nuclei for the subscale oxide should depend largely upon the concentration of oxygen in the metal phase, since there is always a relatively abundant supply of copper atoms. It is to be expected that the solubility of oxygen should increase with increasing noble metal content, so that there should be a greater number of oxygen atoms available to form nuclei, hence a larger number of particles and a smaller particle size.

The grain boundary preference is probably primarily a result of preferential nucleation of the oxide precipitate at the grain boundaries, rather than higher rates of diffusion in the grain bound-

Fig. 15—Schematic representation of the partial pressure of oxygen as a function of distance, Cu-Pd alloys.

aries, since the effect of temperature is opposite to that expected in the latter case.

The presence of voids in the  $\text{Cu}_2\text{O}$  scale may be tentatively explained in the following way. Copper can diffuse toward the scale through the metal and the oxide phases of the subscale, while the noble metal can diffuse in the opposite direction only through the metal phase. Thus in the metal phase of the subscale there is an unequal transport of copper and noble metal, which is believed to be possible only if a stream of lattice vacancies flows in the direction opposite to that of the most rapidly diffusing component, here the noble metal. The vacancies, having passed through the subscale may then enter the scale, and there collect to form voids.

**Kinetics:** In considering the treatment of the kinetic data it is appropriate to inquire into the possibility of the application of Wagner's analysis, since it would presumably be applicable if the amount of oxygen in the subscale were negligible compared to the total amount involved in the oxidation process. The fraction of oxide in the external scale,  $\alpha$ , is given by:

$$\alpha = \sigma \sqrt{\frac{K_E}{K_m}} \quad [4]$$

where  $\sigma$  is a constant calculated from densities and molecular weights. Values of  $\alpha$  are shown in Figs. 16 and 17, where it may be seen that the relative amount of oxygen involved in the subscale increases with increasing noble metal content, and may reach a value of 2/3; i.e.,  $\alpha = 0.33$ . Evidently the relative amount of oxygen in the subscale is not negligibly small, and Wagner's analysis cannot be applied, at least not in its entirety.

Kinetic equations for the growth of scale and subscale were derived on the basis of the model shown in Fig. 18.† Copper diffuses from the alloy to the

Fig. 16—Relative amount of oxygen in the external scale, Cu-Pd alloys.

alloy/subscale interface at which point the concentration is  $C_1$ . From the alloy/subscale interface to the subscale/scale interface, copper diffuses in the metal phase of the subscale as a result of the concentration gradient  $(C_1 - C_2)/S$ . Diffusion of copper in the external scale results from the concentration gradient  $(C_3 - C_4)/E$ . Reaction with oxygen takes place at the scale/oxygen interface, the thin layer of  $\text{CuO}$  being neglected. The subscale forms as a result of the inward diffusion of oxygen along the gradient  $(C_5 - C_6)/S$ , the oxygen having originated by dissociation of  $\text{Cu}_2\text{O}$  at the scale/subscale interface. It is convenient to use the initial gas/metal interface as the origin of the distance coordinate. Thus  $v$  is the thickness of metal oxidized to  $\text{Cu}_2\text{O}$  and  $p$  is the distance of the subscale/alloy interface from the initial surface. Although the model chosen involves the oxide  $\text{Cu}_2\text{O}$ , it is obvious that the result can be generalized. It is assumed that the concentration gradients in the scale and

Fig. 17—Relative amount of oxygen in the external scale, Cu-Pt alloys.

subscale are linear, that the subscale oxide particles offer no barrier to diffusion, and that both scale and subscale grow parabolically according to eqs 2 and 3. The concentrations  $C_1$ ,  $C_2$ ,  $C_3$ ,  $C_4$ ,  $C_5$ , and  $C_6$  are assumed independent of time for a given alloy and a given set of environmental conditions. A derivation based on Fick's law leads to the following equations:

$$\sqrt{K_E} = \frac{D(C_3 - C_4)}{\frac{\epsilon(C_5 - C_6)D_o}{\sqrt{K_E}} + \frac{C_2\sqrt{K_E}\delta}{2}} \quad [5]$$

$$\sqrt{\kappa} = \frac{2D(C_3 - C_4)}{\sqrt{K_E}(C_0 - C_1)} \frac{(1 - 2D_M)}{\kappa} \quad [6]$$

$$\sqrt{\kappa} = \delta\sqrt{K_E} + \sqrt{K_E} \quad [7]$$

where  $D$  is the diffusion coefficient for copper ions in  $\text{Cu}_2\text{O}$ ;  $D_M$ , the diffusion coefficient for copper in the alloy;  $D_o$ , the diffusion coefficient for oxygen in the metal phase of the subscale;  $\epsilon = 2$  atomic wt of copper divided by atomic wt of oxygen;  $\delta = \frac{Q_{\text{Cu}_2\text{O}} \cdot 2W_{\text{Cu}}}{Q_{\text{Cu}} \cdot W_{\text{Cu}_2\text{O}}}$ , in which  $Q$  is the density in g per cu cm and  $W$ , formula weight; and  $\kappa$  is defined by:  $p^2 = \kappa t$ . The concentration terms are as

indicated in Fig. 18. Eq. 6 is subject to the restriction that  $\frac{\kappa}{2D_M}$  is large, otherwise the last term be-

comes more complex. If the concentration terms and diffusion coefficients were known it would be possible to solve eqs 5, 6, and 7 simultaneously for  $K_E$  and  $K_S$ . However, since some of the constants are not known it is necessary to treat eqs 5 and 6 separately. Since eq 5 is a quadratic in  $\sqrt{K_E}$  if  $K_S$  is taken as a known constant, it is possible to substitute values of the various terms as follows: The values of  $C_5$  and  $D_o$  are taken as the values for pure copper given by Rhines and Mathewson<sup>8</sup> and assumed independent of the alloy composition;  $C_6$  was assumed to be zero.  $C_2$  was measured for one alloy and calculated as a function of alloy composition using an independent equation which is due to Wagner.

$$\frac{K_E}{K_{E(\text{Cu})}} = \frac{1 - \sqrt{\frac{C_B}{C_2}}}{1 - \sqrt{C_B}} \quad [7]$$

where  $K_{E(\text{Cu})}$  is the parabolic rate constant for unalloyed copper;  $C_B$ , the mol fraction of the alloy phase in equilibrium with the oxide phase and an external oxygen pressure  $P_{\text{O}_2}^a$ .

The values of  $C_2$  obtained from this equation are shown in Fig. 19. The quantity  $D(C_3 - C_4)$  was calculated assuming that the quantity  $(C_3 - C_4)$  is pro-

portional to  $(C_2 - C_B)$  and that  $D$  is independent of the composition of the oxide. The term  $K_B$  was taken as a known constant, using the experimental values. The value of  $K_B$  so calculated from eq 5 are given in Table VI together with the experimental values. The agreement is quite good. While it is recognized that this agreement is in part due to the fact that experimental values of  $K_B$  and values of  $C_2$  calculated from  $K_B$  and  $K_S$  by means of an independent equation were employed, it is evident that eq 5 is valid. The relative magnitude of the various terms in eq 5 is such that the rate constant for the external scale is largely dependent upon diffusion of copper in the alloy. The fact that  $D_M$  does not appear explicitly in eq 5 is not significant, since its effect is exerted through the choice of  $C_2$  and  $K_B$ .

Eq 6 cannot be treated in the same way as eq 5 since the quantity  $C_1$  is not known. Under the circumstances all that can be done is to insert experimental values of  $\chi$  and  $K_B$ , calculate  $C_1$ , and judge whether the result is reasonable. The quantity  $D(C_3 - C_4)$  was calculated as for eq 5, and values of  $D_M$  were taken from the work of Thomas and Birch- enall<sup>9</sup> as follows:  $1.7 \times 10^{-10}$  cm<sup>2</sup> per sec at 1000°C,  $5.8 \times 10^{-11}$  cm<sup>2</sup> per sec at 925°C, and  $1.73 \times 10^{-11}$  cm<sup>2</sup> per

sec at 850°C, for mol fraction copper equal to 0.32. The calculated values of  $C_1$  are shown in Table VII in which it is seen that, with but two exceptions, the calculated values of  $C_1$  lie between  $C_0$  and  $C_2$  as they should. Furthermore, the metal at the alloy subscale interface in all specimens was observed to have no trace of copper color, hence  $C_1$  must be less than 0.80 mol fraction copper. The calculated values of  $C_1$  are less than this value. Eq 6 is presumed to be essentially correct inasmuch as it yields reasonable values of  $C_1$ .

It is appropriate to point out that the copper concentration gradient in the subscale is probably the limiting factor for the growth of the external scale, since  $S$  is generally comparatively large. If, as has been assumed, the subscale thickness is mainly determined by the amount of oxygen diffused from the scale/subscale interface, then the copper concentration gradient across the subscale is dependent upon it, and likewise the growth of the external scale. Thus the rate of growth of the external scale is limited more by the small copper concentration gradient in the subscale than by the copper concentration in the unoxidized alloy.

Eqs 5 and 6 have been applied above to the alloys which form  $\text{Cu}_2\text{O}$  in the scale and subscale. These equations could also be applied to the case in which the scale and subscale oxide are  $\text{CuO}$ . In this case the dependence of  $K_B$  upon the alloy composition

Fig. 18—Concentration gradients arising during the oxidation of a base metal-noble metal alloy as typified by the Cu-Pd alloys.

would be expected to be similar to that for the case in which only  $\text{Cu}_2\text{O}$  occurs. This is verified in Fig. 9. The transition from  $\text{Cu}_2\text{O}$  to  $\text{CuO}$  in the scale and subscale with increasing palladium content (decreasing  $C_0$ ) is pictured as follows. For the alloys high in copper, the stationary copper concentration  $C_2$  at the scale/subscale interface is maintained at a value greater than the equilibrium value,  $C_B$ . As  $C_0$  decreases, a place is reached where diffusion of copper to the scale/subscale interface can no longer maintain  $C_2$  greater than  $C_B$ . Then the scale becomes  $\text{CuO}$ , and  $C_2$  is less than  $C_B$ , but greater than  $C_B'$ , where  $C_B'$  is the copper concentration in equilibrium with  $\text{CuO}$ . When  $C_2$  is only slightly less than  $C_B$ , and  $C_1$  is greater than  $C_B$ , the external scale would be  $\text{CuO}$  and the subscale oxide  $\text{Cu}_2\text{O}$ . This is the transition case between the first case in which only  $\text{Cu}_2\text{O}$  is found and the second case in which only  $\text{CuO}$  is found. As  $C_0$  is further decreased, a point will be reached where  $C_2$  can no longer be main-

Fig. 19—Stationary Cu concentration at the scale/subscale interface, calculated. Cu-Pd alloys with  $\text{Cu}_2\text{O}$  scale. Experimental points represented by X.

tained at a value greater than  $C_s'$ . At this point the oxide (probably containing considerable copper) appears.

It is believed that the kinetic equations could be applied to other binary solid solution systems in which the affinity of the solvent toward oxygen is much greater than that of the solute. In this connection it is noted that platinum is more noble than palladium, and yet no fundamental difference is found between the oxidation of their alloys with copper. As a matter of fact, palladium appears to deviate sufficiently from nobility that the oxidation of Cu-Pd alloys may be considered as a connecting link between the ideal base metal-noble metal case and the base metal-base metal case of alloy oxidation.

The effect of the diffusion coefficient in the alloy upon the oxidation rate is shown by comparing the oxidation rates and diffusion rates for Cu-Pd and Cu-Pt alloys. This cannot be discussed quantitatively on the basis of eqs 5 and 6 since, in passing from one system to the other, the concentration terms for copper and oxygen, and the diffusion coefficient for oxygen in the metal change. Diffusion coefficients for the Cu-Pt system extrapolated from the data of Kubaschewski and Ebert<sup>10</sup> are from 0.03 to 0.05 times the corresponding values for the Cu-Pd alloys. It is to be expected then that the copper concentration  $C_1$ ,  $C_2$ , and  $C_3$ , would be smaller for the Cu-Pt alloys. This would, of course, result in a smaller rate of delivery of copper to the scale/oxygen interface, hence a smaller value of  $K_s$ . That this is the case may be seen in Fig. 12.

The temperature dependence of the rate constants  $K_s$  and  $K_{ss}$  is generally not of the Arrhenius type. There is no reason to expect an Arrhenius type dependence, because of the fact that the concentration terms in eqs 5 and 6 do not follow such a temperature dependence.

Wagner's theory for the oxidation of binary alloys containing one noble metal results in two equations, one of which (eq 7) has been used successfully here. This equation does not involve the diffusion coefficient for the alloy. The other equation involves the diffusion coefficient in the alloy and disregards subscale formation. The latter equation does not fit the experimental data.

### Conclusions

1—The oxidation of Cu-Pd and Cu-Pt alloys has been studied as a function of composition and temperature from the standpoint of the kinetics of scale and subscale growth and the structure and morphology of the reaction products. Under the conditions of the experiments a subscale is always formed beneath the external scale. Rate constants for the external scale thickness decrease regularly with increasing noble metal content in the alloy. Rate constants for the subscale thickness pass through a maximum which occurs at higher noble metal content the higher the temperature of oxidation for the Cu-Pd system, and which is independent of temperature for the Cu-Pt system. The rate constants generally do not follow a temperature dependence of the Arrhenius type.

2—The scale and subscale structure has been discussed in terms of a necessarily schematic equilibrium diagram for the two metals and oxygen.

3—The morphological features of the scale and subscale have been discussed. Chief among these is

the preferential precipitation of oxide at grain boundaries in the subscale.

4—In addition to previously published<sup>7</sup> criteria for subscale formation the further criterion that noble metal must go into solid solution in the base metal oxide must be considered in order to explain the formation of a subscale in alloys with noble metals.

5—Kinetic equations for the rate constants for the scale and subscale involving concentrations of the various diffusing elements and diffusion coefficients for the base metal and oxygen in the alloy, and the base metal in the oxide have been derived.

6—Calculations based on the kinetic equation for the external scale agree with the experimental data. Calculations based on the kinetic equation for the subscale yield reasonable results, but this equation must be considered less firmly established than that for the external scale.

7—The rate constant for the external scale is primarily governed by diffusion of the base metal through the subscale zone. The rate constant for the external scale and the diffusion coefficient in the metal phase are smaller for the Cu-Pt alloys than for the corresponding Cu-Pd alloys.

8—The rate constant for the subscale is largely determined by the inward diffusion of oxygen to the subscale/alloy interface.

9—The kinetic equations are believed to be applicable to the oxidation of solid solution alloys of a base metal and a metal considerably more noble.

10—One of the equations of Wagner appears to be applicable to the present case; the other leads to results not in agreement with experimental measurements.

11—A subscale was observed to form in a Ni-Pt alloy, but is less extensive than that found in the Cu-Pd and Cu-Pt alloys.

### Acknowledgments

The granting of a graduate fellowship by the International Nickel Company is gratefully acknowledged. The author is grateful to the faculty of the Department of Metallurgical Engineering, Carnegie Institute of Technology, particularly to R. F. Mehl and C. E. Birchenall, for valuable suggestions. Thanks are due to John Chirigos, who assisted in the laboratory, and to Mrs. Martha M. Helzel and Mrs. Elizabeth Duncan, who carried out the chemical analyses. The diffusion work alluded to was sponsored by the Office of Naval Research.

# Plasticity of Molybdenum Single Crystals

by N. K. Chen and R. Maddin

In the extension of molybdenum single crystals at room temperature, the slip planes were found to be of the type  $\{110\}$ ; the slip direction  $\langle 111 \rangle$ . Theories of plasticity of body-centered cubic metals have been examined, and an explanation based upon planes of highest atomic density seems plausible to explain the plastic behavior of molybdenum single crystals.

IN body-centered cubic metals, slip has been reported to occur on several planes; these are of the type  $\{110\}$ ,  $\{112\}$ , and  $\{123\}$ . Andrade has correlated<sup>1</sup> the operative slip planes in body-centered cubic metals with the testing temperature relative to the melting point. In this correlation, if  $T$  is the absolute temperature at which slip takes place and  $T_m$  the absolute melting point, then the acting slip planes in body-centered cubic metals may be arranged as shown in Table I. However, deviations from this correlation have been reported in iron and iron-silicon alloys<sup>2</sup> and also in molybdenum deformed at a temperature around 2400°C.<sup>3</sup>

In the case of iron and other body-centered cubic metals or alloys in which all three slip planes have been reported to be active at any one temperature, the crystallographic mechanism of slip is not well understood. Numerous investigators in this field have assumed that the resolved shear stress is a deciding factor. Such considerations were given by Gough in his experiments with repeated torsion of iron single crystals<sup>4</sup> and recently by Opinsky and Smoluchowski in their study of iron-silicon alloys,<sup>5</sup> and will be dealt with later in this report.

A third possibility is that slip lines in body-centered cubic metals may be formed by alternate slip on nonparallel  $\{110\}$  planes and not by slip on any plane of higher indices. This was advanced by Elam in the case of  $\beta$  brass.<sup>6</sup> Since  $\{110\}$  planes are planes of highest atomic density in the body-centered cubic structure, this hypothesis would be in accordance with the plastic behavior of metals in other systems, namely, face-centered cubic and hexagonal close-packed. Experimental evidence in support of this hypothesis is lacking. Nevertheless the work of Barrett, Ansel, and Mehl<sup>7</sup> has definitely

Table I. Arrangement of Acting Slip Planes in Body-Centered Cubic Metals

| Metals                | $T/T_m$   | Slip Plane |
|-----------------------|-----------|------------|
| W, Mo, Na             | 0.08-0.24 | $\{112\}$  |
| Mo, Na, $\beta$ brass | 0.26-0.50 | $\{110\}$  |
| Na, K                 | 0.80      | $\{123\}$  |

demonstrated that the slip resistance on  $\{110\}$  planes in iron is very much smaller compared with that on  $\{112\}$  and  $\{123\}$  planes.

In the present investigation, molybdenum single crystals were carefully documented as to the operative slip planes and lattice reorientations after plastic extension at room temperature. In three crystals studied,  $\{110\}$  planes were found to be active invariably rather than the  $\{112\}$  planes, which were previously reported for molybdenum at this temperature<sup>7</sup> and predicted by Andrade's theory.<sup>1</sup>

In two other cases  $\{112\}$  and  $\{123\}$  planes seemed to operate together with  $\{110\}$  planes as active slip planes. However, it is believed, after careful analysis of crystallite and lattice rotations, that slip on  $\{112\}$  and  $\{123\}$  planes may be spurious. Particular reference will be made to the formation of asterism, lattice rotation, and crystallite rotation in an attempt to show that slip apparently observed on  $\{112\}$  and  $\{123\}$  planes is actually slip on nonparallel  $\{110\}$  planes.

## Materials and Treatment

Sintered molybdenum rods  $\frac{1}{8}$  in. in diam, obtained from the Fansteel Metallurgical Co., were reported to have a purity of 99.9 pct.\* One specimen, Mo-13,  $\frac{1}{4}$  in. in diam, was supplied by Westinghouse Electric Corp.

Single crystals were prepared, using the technique devised by Chen, Maddin, and Pond.<sup>8</sup> Mo-13 was  $\frac{1}{4}$  in. in diam x 7 in. long with a reduced gage section of 0.200 in. in diam x 3 in. long. The center of

\* C 0.001  $\pm$  0.001 pct (as-received).

C 0.003  $\pm$  0.001 pct single crystal (Battelle Memorial Institute).

N. K. CHEN and R. MADDIN, Junior Members AIME, are Research Associate in Metallurgy and Assistant Professor of Metallurgy, respectively, The Johns Hopkins University, Baltimore.

Discussion on this paper, TP 3156E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, June 25, 1951. New York Meeting, February 1952.

Fig. 1—Orientations of crystals investigated.

The orientations of Mo-13 and M-15 after the first and second extension, and of M-6 after the first, second, third, fourth, and fifth extension are included.

the gage section contained a single crystal  $1\frac{1}{4}$  in. in length. All other specimens, M-6, M-15, M-25, and M-12, were  $\frac{1}{8}$  in. in diam x 7 in. long, with single crystals approximately 2 to 3 in. in length occupying the entire center sections of each specimen. All specimens were electrolytically polished, using an electrolyte of 300 cc methyl alcohol, 60 cc  $H_2SO_4$ , 130 cc HCl, and a current density of 4 amperes per sq in. The specimens were pulled in a Tinius-Olsen beam-type testing machine using SR-4 type A-8 strain gages and strain indicator. Load values were estimated to within 1 lb. The orientation of each specimen was determined before and after each extension by using an X-ray back-reflection Laue method.

### Determination of Slip Elements

The orientations of all the crystals are shown in Fig. 1 in a standard cubic stereographic projection. The movements of the stress axes for Mo-13, M-6, and M-15 after various extensions, are indicated by the shift in the stress axis to position 1, 2, etc., respectively. The axis shift clearly shows a rotation toward the direction  $[\bar{1}\bar{1}1]$ , which is the slip direction in these three crystals. It was noted that both M-6 and M-15 rotated toward the  $[\bar{1}\bar{1}1]$  direction

a—Before extension.                      b—After extension to yield.

even when the symmetry curve, represented by the line joining (001) and  $(0\bar{1}1)$ , was reached by the stress axes. This may be due to an insufficient amount of slip on the conjugate slip plane, (101), so that the path of stress-axis rotation did not revert toward the direction  $[\bar{1}\bar{1}1]$ . Microscopic examination showed that the second slip system, (101), was not prominent even at the end of the fourth extension of M-6 and the last extension of M-15 (cf. Fig. 5b and c).

Crystals M-25 and M-12 behaved differently from those mentioned above. Their behaviors will be analyzed separately in the following sections.

At the early stage of deformation, the slip lines were quite straight and uniformly dispersed, though very faint, resembling striations. An alteration of the Laue spots, indicating the initial stage of "asterism," was invariably observed in all specimens when they were extended to just beyond their yield. A set of typical photograms from Mo-13 before and after extension is shown in Fig. 2a and b. Slip lines were very difficult to observe at the yield because of the fineness of the lines, whereas a decided change in the Laue reflection could easily be noted (cf. Fig. 2b). In correlating slip traces measured on the metallograph with the orientation determined from X-ray, the orientation of the specimens after deformation was always used.

Fig. 3—Projection showing orientation of Mo-13. Specimen axis SA, horizontal. SP and SD represent the observed slip plane and slip direction; 1 to 12 represent the 12  $\{112\}$  planes.

Fig. 4—Determination of the pole of the slip traces, M-6. Stress axis SA, at the center of projection, and X-ray beam containing the reference mark RM is perpendicular to stress axis.  $P_0$  is the initial orientation. a (upper left)—After the first extension. b, c (upper center, upper right), d, e, f (middle left, center, right), and g (lower left)—After the fourth extension at different positions around the periphery of the crystal.

It was found in three specimens, Mo-13, M-6, and M-15, that the  $(\bar{1}01)$  plane, the plane of highest resolved shear stress, was responsible for the observed slip markings, rather than any of the  $\{112\}$  planes as previously reported.<sup>7</sup> This was carefully checked and can be illustrated with the aid of Fig. 3 (specimen Mo-13), which shows, in projection, one plane of observation in which all 12 possible  $\{112\}$  planes

are marked. If the angle which the slip line makes with the stress axis, in the counterclockwise sense, is considered positive, the angles which the 12  $\{112\}$  planes make in the plane of observation are shown in Table II.

It can be seen that no one of the 12  $\{112\}$  planes gives an angle for slip marking in the observed direction within  $20^\circ$  of the measured slip line angle ( $51^\circ$  positive). Similar analyses were carried out in other planes of observation and the  $(\bar{1}01)$  plane was invariably obtained as the active plane of slip.

In the case of M-6, measurements were made at each  $15^\circ$  around the specimen axis on the metallograph. An indicator was attached to the specimen along a reference mark that was also used for the orientation determination by X-rays. The angle of rotation was measured on a protractor attached to the stage of the metallograph as given by the indicator. The angle between the specimen axis and the slip marking was measured on the metallograph at a magnification of X250. Thus, by plotting stereo-

graphically the pole representing the slip traces on each plane of observation, the position of the pole of the slip plane could be directly located at the intersections. For M-6, it was a small region, again clustered around the  $(101)$  pole, which is predicted as the plane having the highest resolved shear stress, Fig. 4. Fig. 5a to g represents the appearance of slip markings at different positions around the crystal. It should be noted that lines at the head of the glide ellipse are wavy in character, but those at a position approximately parallel to the slip direction are fairly straight. Conjugate slip lines could be witnessed in some areas as shown in Fig. 5b and c. They were determined to be  $(101)$  planes.

To check the crystallographic location of slip

Fig. 8—Projection of M-12 showing the pole of observed slip traces, the axes of rotation determined from asterism, and the stress axis movement.

planes in M-6, an X-ray photogram was taken with the beam adjusted perpendicular to the plane containing the specimen axis and the minor elliptical axis. Fig. 6 indicates such a photogram having pronounced asterism. On plotting stereographically (Fig. 7), it is clearly seen that  $(101)$  plane should be the operative slip plane and  $[111]$  the slip direction, in order to account for the crystallite rotations occurring about the observed axis  $[121]$ , which is in the slip plane and  $90^\circ$  from the slip direction. This type of crystallite rotation has been reported in the deformation of many metal single crystals.<sup>9</sup>

The pole of observed slip traces in M-12, as

Fig. 9—Slip lines in M-12 after extension to shear failure.

a, b, c (upper left, upper right, lower left)—X500. d (lower right)—X2000.

determined by the optical method after the first extension, was very close to (112) as shown in Fig. 8. After the second extension, the specimen failed in a ductile manner, and the stress axis moved to the position 2 toward the  $[\bar{1}\bar{1}1]$  direction. The traces of a second system, which could be viewed only at a few locations, when plotted stereographically, appeared to be due to slip on the (011) plane. The participation of this plane was very slight and was difficult to observe. Representative micrographs of the slip lines are shown in Fig. 9a to d.

The observed location of slip traces shown in Fig. 8 after the first extension was checked by the X-ray method and analyzed according to the same technique used in Fig. 7. However, as indicated in Fig. 8, the expected axis of rotation in the plane (112) and  $90^\circ$  from the slip direction C was not observed. Instead, there appeared a well-defined axis of rotation which could be described only if the slip plane was (011) and the slip direction  $[\bar{1}\bar{1}1]$ , I-C in Fig. 8. This result appears more rigorous when the asterism in Fig. 10b is plotted stereographically. (Fig. 10a shows the initial orientation.) Careful examination indicated that the main asterism (Fig. 10b) in the approximately horizontal direction could be viewed as composed of at least two parts as shown enlarged in Fig. 10c. They seemed to represent rotations

a—Before extension.

b—After the first extension.

c—Enlargement of Laue spots in b.  
Fig. 10—Laue photograms of M-12.

about I-C and III-C, respectively (Fig. 8). Thus it is quite probable that the slip traces observed apparently on (112) planes were in reality slip on two {110} planes with a common slip direction.

The results for specimen M-25 are shown in Fig. 11. Here, again, the slip traces observed on the metallograph are shown plotted stereographically as areas in Fig. 11 clustering in the vicinity of the (123) pole. In addition, an area as determined from a second set of slip traces is shown clustering near the (011) pole. Based upon the slip traces as determined from metallographic observation, it would be said that the specimen had slipped on (011) and (123) [and/or (112)] planes. However, lattice and crystallite rotations shown in the photograms of Fig. 12a and b indicate, when plotted stereographically, that the planes of slip are actually (011) and (011); the slip systems being I-C and II-A respectively in Fig.

Fig. 11—Projection of M-25 showing the pole of the observed slip traces, the axis of rotation determined from asterism, and the stress axis movement.

11. It is difficult to explain the movement of the stress axis  $P_0$  to  $P_1$ , if slip had occurred only on (123)  $[\bar{1}\bar{1}1]$  (and/or (112)  $[\bar{1}\bar{1}1]$ ). If, however, slip had occurred on systems I-C and II-A, as indicated, the movement  $P_0$  to  $P_1$  could be rationalized by resolving it into two components moving towards A and C respectively.

In order to check carefully whether the asterism from which the crystallite rotations were determined was characteristic of the entire specimen or was indicative only of localized areas, a series of X-ray photograms was made at various positions along the specimen axis and around the periphery of the crystal. It was found that the asterism characteristic of one position was the same when a photogram was made  $180^\circ$  opposite to the first position.<sup>†</sup> In addition to the asterisms from which were determined the slip systems I-A and II-C, a third type was observed in a photogram which was taken  $63^\circ$  in azimuth from the reference mark (Fig. 12b). In an attempt to check the crystallite rotation at this position with the rotations previously determined, it was noted that the pronounced asterism in this position could only be accounted for by a rotation about the pole of the slip plane I (Fig. 13). From this it must be realized that a number of photograms must be made around the periphery of the specimen in order to detect the different lattice rotations involved in the deformation of the specimen. This is so, because at certain positions the distortions of the Laue spots indicative of different types of rotation may be superimposed on each other. Conse-

a—Plotted in Fig. 11.

b—Plotted in Fig. 13.

Fig. 12—Laue photograms taken at different positions around M-25 after extension.

<sup>†</sup> This indicates that the asterism is crystallographic in nature and represents a true account of plasticity in the specimen.

quently, the analysis at these positions becomes difficult.

At the head of the glide ellipse, the wavy character of the slip traces could be resolved into a series of saw-toothed markings. At a position away from the head, slip lines appeared to be clustered. The general direction of the cluster was used for the determination of the slip plane (see Fig. 11). However, when the fine lines of the cluster were plotted, they proved to be near a (011) pole.

### Stress-Strain Data

No attempt has been made to resolve the critical

Fig. 14a—Stress-strain curves for M-6 after the first, second, and third extension.

shear stress, since, in specimens Mo-13, M-6, and M-15, the plane acting was the one of highest resolved shear stress, i.e.  $(\bar{1}01)$   $[\bar{1}11]$ ; but in specimens M-12 and M-25, there was more than one system acting. The stress-strain curves for the first, second, and third extensions are shown in Fig. 14a. The modulus of elasticity,  $E$ , was determined to be about  $20 \times 10^6$  psi for these curves. A plot of stress at yield vs. elongation is shown in Fig. 14b.

Specimen M-12 failed during the second extension with a typical ductile fracture as may be seen in Fig. 15a and b. The elongation at fracture was about 65 pct.

### Discussion

In view of the results reported herein, it is difficult to explain the behavior of molybdenum single crystals on the basis of Andrade's theory. His theory would predict that slip in molybdenum at room temperature would occur on  $\{112\}$  planes. Although Tsien and Chow<sup>7</sup> reported slip in molybdenum single crystals at room temperature on the  $\{112\}$  planes, only one crystal was investigated; whereas in the present work five specimens are shown to slip on  $\{110\}$ . Moreover, more than one method was used to determine the slip elements in the present work. It is realized that the work of Tsien and Chow involved the extension of molybdenum single crystals 0.25 mm in diam, whereas the present work used  $\frac{1}{8}$  and  $\frac{1}{4}$  in. specimens. It may be that the disagreement between their work and the present work is due to the difference of specimen size. It is contemplated to investigate molybdenum single crystals of very small size in the near future.

A number of investigators<sup>4-5</sup> have attempted to explain the activity of the slip elements on the basis of systems of highest resolved shear stress. For example, Opinsky and Smoluchowski<sup>5</sup> have computed mathematically the areas for systems,  $\{110\}$ ,  $\{112\}$ ,

Fig. 14b—Stress at yield vs. elongation (strain-hardening curve).

and  $\{123\}$  in the direction  $\langle 111 \rangle$ , which have the highest resolved shear stress. In Fig. 16 there is shown a stereographic projection containing the areas of highest resolved shear stress with reference to the three types of planes reported to be active in the plasticity of body-centered cubic metals all in the  $\langle 111 \rangle$  direction. This plot was determined by measuring the  $\chi$  and  $\lambda$  values, where  $\chi$  is the angle between the slip plane and stress axis and  $\lambda$  is the angle between the slip direction and stress axis, for 94 different orientations covering the unit triangle. The plot is essentially in agreement with that produced by Opinsky and Smoluchowski. The Wulff net used here had an accuracy of  $\frac{1}{4}^\circ$ , and, thus, the boundaries shown in Fig. 16 are within an accuracy of  $\frac{1}{2}^\circ$ . It may be seen from Fig. 1, that specimen Mo-13 falls within the area devoted entirely to  $(\bar{3}\bar{1}2)$  slip, yet the observed slip plane was conclusively  $(\bar{1}01)$ . In the specimens M-12 and M-25 the  $(\bar{1}01)$ , the plane of highest resolved shear stress, was not observed.

M-15 should slip on both  $(\bar{1}01)$  and  $(213)$ , yet slip was found to occur only on  $(\bar{1}01)$ . Furthermore using the data on silicon-ferrite obtained by Opinsky and Smoluchowski,<sup>6</sup> it may be seen, Fig. 17, that there are many cases of disagreement with the predicted slip plane based upon highest resolved shear stress. This, of course, may be explained on the basis that the slip resistance on the three planes is not equal, as stated by Opinsky and Smoluchowski.

Fig. 15—Two views of shear failure in M-12. X2.

If, however, their explanation is valid, it must take into account the behavior of M-25 and M-12.

In the case of M-25, observation of the slip traces appeared to indicate that slip had occurred on the planes  $(123) [\bar{1}\bar{1}1]$  and  $(0\bar{1}1) [\bar{1}\bar{1}1]$ . The resolved shear stress on both these systems was calculated,

and the ratio of these stresses is  $\frac{(123) [\bar{1}\bar{1}1]}{(0\bar{1}1) [\bar{1}\bar{1}1]} = 1.07$ .

Again for M-12, the observation of slip traces appeared to indicate that slip had occurred on the plane  $(112) [\bar{1}\bar{1}1]$  and  $(0\bar{1}1) [\bar{1}\bar{1}1]$ . The resolved shear stress on both these systems was calculated,

and the ratio of these stresses is  $\frac{(112) [\bar{1}\bar{1}1]}{(0\bar{1}1) [\bar{1}\bar{1}1]} = 1.06$ .

However, the participation of the plane  $(0\bar{1}1)$  in both crystals appeared to be very slight, and the plane  $(\bar{1}01)$  is not observed. For a valid comparison,

the ratio  $\frac{(123) [\bar{1}\bar{1}1]}{(0\bar{1}1) [\bar{1}\bar{1}1]}$  would have to be measured,

Fig. 16—Areas of highest resolved shear stress in the body-centered cubic lattice considering  $\{110\}$ ,  $\{112\}$ , and  $\{123\}$  planes in direction  $\langle 111 \rangle$ .

for the case of M-25 the ratio  $\frac{(112) [\bar{1}\bar{1}1]}{(0\bar{1}1) [\bar{1}\bar{1}1]}$  would

have to be measured, rather than the ratio  $\frac{(112) [\bar{1}\bar{1}1]}{(\bar{1}01) [\bar{1}\bar{1}1]}$ , as shown in Fig. 1 for this boundary.

Consequently, it would seem very difficult to document the activity of two types of planes, unless they are the correct ones and are operating simultaneously at the yield of the specimen with no lattice rotations involved.

A possible explanation for the operating slip systems may be based upon a consideration of the plane of the highest atomic density. It is to be noted that in face-centered cubic and hexagonal close-packed metals, the plane of maximum atomic density is always the one to operate. In the body-centered cubic metals, the plane of highest atomic density is  $\{110\}$  and of successively decreasing atomic density,  $\{001\}$ ,  $\{112\}$ ,  $\{111\}$ , and  $\{123\}$ . Since the direction  $\langle 111 \rangle$  is seldom in question as the

Fig. 17—Plot of data from Opinsky and Smoluchowski<sup>6</sup> within areas of highest resolved shear stress.

slip direction, the {001} and {111} planes can be discounted, since they do not contain this direction.

In the present investigation, the highest atomic density theory can be used conclusively to explain the behavior of Mo-13, M-6, and M-15, although there may be some doubt for M-12 and M-25 if only the optical data are considered. However, a number of pertinent facts must be considered before slip can be said to have occurred on low atomic density planes. For example, when the pole of the slip plane is obtained by the intersection of only two traces, there can be no scatter to the observed pole, despite the fact that the slip traces in body-centered cubic metals are inherently wavy. When the pole of the slip plane is obtained by plotting many traces, an area results. If this area falls in the vicinity of {112} pole, then that plane is reported as the plane of slip (cf. Fig. 8). If the area falls in the region of {123}, then this pole is generally reported to be the plane of slip (cf. Fig. 11). All of the past data have been reported generally with the understanding that measurements of the direction of wavy slip lines involve considerable error. Despite the fact that the microscopic appearance of slip traces must have represented the movement of atomic planes, these traces usually cannot be resolved with the optical microscope and hence may represent the integrated effect of more than one slip plane. It is suspected that the behavior of two nonparallel {110} planes would not present an integrated {110} trace; but might, under certain conditions, represent a {112} trace or a {123}. For example, if one of the two active {110} planes is predominant, the resulting trace could be {112}.

In the determination of slip elements, it seems more conclusive to consider the alterations in the structure as evidenced by the formation of asterism as a result of plastic deformation. It is to be expected that asterism would more nearly represent the structural changes occurring during deformation and would be a more sensitive indication, since it need not represent a grossly integrated condition as may be the case with the observation of slip traces.

In the present investigation, stereographic analysis of the asterism yields highly reproducible results. Invariably the axis about which rotation has taken place to produce the asterism is in a {110} plane. This points strongly to the condition that slip has occurred on planes of the type {110}, since the rotation of the slip plane toward the stress axis is about an axis in the slip plane and generally at right angles to the slip direction. The rotation axes determined in this manner were at right angles to  $\langle 111 \rangle$  directions.

It is interesting to note that Greninger stated in discussion to the paper by Barrett, Ansel, and Mehl that:<sup>2</sup>

"Is it not possible that traces corresponding approximately with {112} or {123} are really composites of alternate slipping on two or more {110} planes? All of these planes contain  $\langle 111 \rangle$  directions, and each {112} plane bisects the angle between {110} planes; likewise each {123} plane is located between a {110} and a {112} plane. Thus if slip were to proceed by approximately equal minute displacements along both  $(1\bar{1}0)$  and  $(01\bar{1})$ , the 'slip line' might appear as an approximate  $\{121\}$  trace; if the relative displacements were 4:1 (instead of being equal) the 'slip line' would be approximately  $\{2\bar{3}1\}$ ."

Recently Gouzou<sup>10</sup> stated that the success of the hypothesis that body-centered cubic metals slip uniquely on {110}  $\langle 111 \rangle$  systems appears to favor

the conclusion that slip on less densely populated planes is spurious and is actually duplex slip on {110}  $\langle 111 \rangle$  slip systems.

It is not completely understood at the present time why specimens Mo-13, M-6, M-15 show the active slip planes to be {110} unequivocally, both from the analysis of slip lines and asterism, whereas M-12 and M-25 behaved differently. It may be that the influence of orientation, on the distribution of shear stress, produces a change in distribution so as to affect the rotations of the slip planes and hence the character of slip traces.

It seems important to study carefully the formation and character of the slip lines with increasing deformation and as a function of orientation. It is contemplated to continue the work along this approach and to include careful investigations of other materials such as tungsten, niobium, and tantalum in an attempt to determine the parameters of plasticity of body-centered cubic metals.

### Conclusions

1—It has been found that molybdenum single crystals slip on the planes {110} in the direction  $\langle 111 \rangle$  for the specimens investigated to date.

2—An explanation for the participation of slip systems based upon temperature is held not tenable, at least in the case of molybdenum.

3—An explanation based upon systems of highest resolved shear stress does not appear to be conclusive, since, in the present work and others cited, cases of disagreement are observed.

4—An explanation based upon planes of highest atomic density, i.e., {110}, seems plausible to explain in part the plastic behavior of molybdenum single crystals.

# Work Hardening-Reannealing Cycle of Pure Silver

by Marian Balicki and Goldye Leeds

A SURVEY of literature reveals the scarcity of experimental evidence relating to work hardening and reannealing of silver.<sup>1-10</sup> With the exception of the well-known X-ray investigation of silver and other metals by W. A. Wood,<sup>11</sup> the effect of progressive cold working has not been studied. The determination of thermal stability of silver in the work-hardened state by means of isochronal or isothermal annealing has been confined apparently to very high reductions only. In the survey made, no study was encountered which endeavored to produce a complete picture of the changes in various properties due to cold working and subsequent reannealing. To fill these gaps and to assemble data that could be used for the determination of activation energies and of frequency coefficients of primary recrystallization, a systematic experimental approach, which was developed by one of the authors, has been applied to pure silver.

## Material and Processing

The silver used was Handy and Harman fine silver, with a spectroscopic analysis at the testing stage of Cu, 0.0001 to 0.001 pct; Te, 0.0001; Pb, Si, Ca, Mg, and Mn, traces. The material was supplied

Table I. Processing of Handy and Harman Silver for Testing

in the form of a rod 0.406 in. diam and was converted into test samples according to the procedure condensed in Table I. It should be mentioned that air annealing was adopted to simulate industrial practice, though it was realized that annealing in a neutral gas or in a vacuum would be preferred.

The usual precautions have been taken to eliminate any structural changes and property changes resulting from the storage of the samples prior to annealing or testing. Thus the wires were kept at the fully annealed stage, and the final wire drawing, which produced the desired degree of work hardening, was done just prior to the final annealing or testing. During the short waiting period, the samples were kept in a thermosflask filled with ice. Even with these precautions some strain-age-hardening or self-annealing could occur.

To test such a possibility, wires of different reductions were prepared in the manner adopted and portions of them were immediately tested. The remaining portions were similarly tested after different periods of storage, both at room and melting-ice temperature. Within experimental error, all samples obtained from a wire of a given percentage of reduction yielded identical values. This result qualified the material for further tests and interpretations, because it showed that either strain-age-hardening and self-annealing were absent, or that these effects fully balanced each other.

The final annealing was carried out in an electric resistance furnace automatically controlled to within  $\pm 10^\circ\text{F}$ . It was realized that the temperature fluctuations were greater than desired for this type of work. To diminish the errors due to fluctuations of temperature, the hot junction of the thermocouple was placed as close to the samples as possible; the time of soaking was reduced to 15 min; and the number of samples annealed at different temperatures was increased.

It will be seen from Table I that some tests were performed on the same material at rising temperature. These will be discussed elsewhere.

Room temperature testing was limited to the determination of some of the mechanical properties that are known to be additive in a degree sufficient to be used for indirect study of the kinetics of the reannealing process.<sup>4</sup> Tensile tests, carried out on a manually operated J. Camillon machine, accurate to within  $\frac{1}{4}$  lb, permitted the determination of the ultimate stress (U.S.) and of the 2 in. elongation, ( $A_2$ ). The proof stress ( $\sigma_p$ ) has been determined from a series of bend tests carried out on a Tinius Olsen Stiffness Tester by using the offset method. This involved accurate determination for each sample of load-angular deflection curves, finding a

Fig. 1—Effect of cold work on properties of pure silver.

$A_2$  is the elongation on 2 in.,  $\sigma_b$ , the proof stress from bending test; U.S., the ultimate stress;  $p_m$ , Krupkowski's strength factor;  $dE/dt$ , the thermoelectric power of couples Ag cold-worked/Ag annealed;  $E_{max}$ , the maximum thermoelectric force developed by the same couples;  $T_1$ ,  $T_2$ ,  $T_3$ , the temperatures of the beginning, middle, and end of recrystallization respectively, all plotted vs. the percentage of reduction produced by room temperature drawing.

load responsible for  $5^\circ$  deflection, and calculating the corresponding stress from the bending formula. Values of proof stress thus obtained would be somewhat higher than those determined from tensile tests. This difference, which is of no real significance for the main purpose of the work, should be attributed to the adoption of a relatively large angle of permanent set, which brings the most stressed portion of the cantilever test piece well inside the plastic range. There, the bending formula, which is valid within the elastic range only, yields inflated values of stress.

### Results

The data obtained have been collected in Appendix 1.\* Figs. 1, 2, and 3 represent the findings graphically. Fig. 1 shows how a number of physical properties of fine silver change by cold working from 0 to 95 pct reduction. Elongation on 2-in. gage length  $A_2$ , for instance, rapidly decreases from its original value of 46 pct to a constant level of 3 pct, at about 21 pct reduction,  $z$ . Ultimate stress, U.S., and proof stress from bending,  $\sigma_b$ , exhibit an almost steady increase, with increasing reduction, though not quite the same in each case. Severe reduction of 95 pct more than doubles the starting values of these properties.

For fuller illustration of the effect of cold working on silver, Fig. 1 contains six additional curves. Two of these, namely, thermoelectric power,  $dE/dT$ , and maximum thermoelectric force,  $E_{max}$ , shown by thermocouples made of silver wires drawn to dif-

ferent reductions,  $z$ , and a standard fully annealed silver wire, show a steady increase as a function of the percentage of reduction. This increase, it will be seen, is very similar to the increase of ultimate and proof stress.

The strength change index,  $p_m$ , introduced by Krupkowski<sup>14</sup> has been calculated from ultimate stress data and values of the percentage of reduction

$z$ , by means of the relationship  $p_m = U.S. \left(1 - \frac{Z}{100}\right)$ .

It may readily be shown that  $p_m = \frac{P_{max}}{F_u}$ , where  $P_{max}$

is the breaking load and  $F_u$ , the section area prior to final wire drawing. It may be seen in the figure that this index slightly increases for low reductions to reach a shallow maximum at about 21 pct. This is followed by a steady decrease, slightly accelerated after 60 pct reduction.

The last three curves in the figure, namely,  $T_1$ ,  $T_2$ , and  $T_3$ , represent, as a function of the percentage of reduction, the characteristic temperatures of primary recrystallization, which is the phenomenon responsible for the main change in properties on reannealing. The data for plotting the  $T_1$  and  $T_3$  curves, illustrating the temperatures of the beginning and of the end of recrystallization, respectively, have been derived from Figs. 2 and 3; while data for the  $T_2$  curve, that is, the temperature of the middle of recrystallization, have been taken from studies of thermoelectric properties at rising temperature. It may be seen that in silver, as in other metals, the temperature range in which the main change in properties takes place on reannealing, is visibly lowered for higher reductions. Unlike other metals studied by this method, however, for reductions greater than 60 pct, silver exhibits an enlargement of the temperature range (vertical distance between  $T_3$  and  $T_1$  curves). It appears that the beginning of recrystallization is decreasing with reduction more rapidly than is the middle and the end of the process (Figs. 2 and 3).

An analysis of all the curves shown in Fig. 1 permits distinguishing three regions of plasticity. The first region between 0 and approximately 21 pct reduction is characterized by rapid increases or decreases in most of the curves. The limit of this region is quite well defined by the percentage of reduction at which elongation reaches its low value and by the maximum in the  $p_m$  curve. The second region between approximately 21 and 60 pct reduction shows a steady run in most of the curves. The border between the second and the third region is not easy to locate. This can best be done with reference to Fig. 4, which is a supplementation of Fig. 1. Wood<sup>15</sup> in his work on silver of similar purity to that used in this study, encountered a growing tendency toward self-annealing after 65 pct reduction, i.e., in the third region of plasticity.

Figs. 2 and 3 show the change in mechanical properties of wires with a selected percentage of reduction caused by 15 min reannealing at different temperature levels. All curves in these figures are well determined by suitably spaced experimental points. The proof stress  $\sigma_b$  curves show least deviation of experimental points, and they appear to be more suited for revealing small differences encountered than are the ultimate stress curves. For instance, proof stress and elongation curves for 80.1 and 60.5 pct reductions (Fig. 2) show quite well a small shift of the main change in the direction ex-

Fig. 2—Change in the mechanical properties of silver cold drawn to 6.0, 21.0, 60.5, and 80.1 pct reduction due to annealing for 15 min at the temperatures indicated.

pected, while the ultimate stress curves exhibit too great a scatter of points to permit any differentiation.

All the curves in Figs. 2 and 3 can be divided into three parts; two almost level and straight portions at low and high temperatures of annealing joined by a third curved portion. The temperature at which the low temperature straight portion joins the curved segment is that of the beginning of primary recrystallization, while the temperature at which the curved segment merges with the second straight portion is that of the end of recrystallization. Observation of the temperatures at which tangents drawn to the straight line portions depart from the curves yields the values of  $T_1$  and  $T_s$ . The temperatures of the beginning and of the end recrystallization obtained from all reannealing curves in Figs. 2 and 3 have been plotted on Fig. 1, using the same markers as in the curves from which they have been derived. There is some scatter of points, but it is not large. It may therefore be concluded that all three properties of the wire with a given percentage of reduction exhibit the main recrystallization change in the same range of temperature.

Microstructure of silver wires with different degrees of cold working has been studied at a magnification of 500X. In general, the structural changes revealed by this work follow the pattern exhibited by other metals on progressive work hardening and reannealing. Because of that only a very brief summary of results needs to be given. In the first region of plasticity, that is, for reductions lower than 21 pct, the microscope revealed the presence of slip lines, as well as a slight departure from equiaxiality of the original crystals. In the second and third re-

Fig. 3—Change in the mechanical properties of silver cold drawn to 16.5, 40.5, 75.0, and 95.0 pct reduction due to annealing for 15 min at the temperatures indicated.

gion of plasticity, a progressively better developed fibrous structure was observed. The effect of annealing was studied on wire with 40.5 pct reduction. Small annealed areas were first observed on samples annealed for 15 min at 225°C. The wire annealed at 250°C produced a structure almost completely free of work-hardened state. These results, when considered together with reannealing curves for  $z = 40.5$  pct in Fig. 3, permit a statement that the change in mechanical properties of cold-worked silver, as in other metals, is due to primary recrystallization; that is, the conversion of the work-hardened structure into a fully annealed, stress-and-distortion-free

Fig. 4—Activation energies  $A$  and frequency coefficients  $C$  of primary recrystallization of cold-drawn silver as a function of the percentage of reduction.

one. As the main change in mechanical and physical properties on reannealing has been ascribed to "recovery" or "relaxation," it follows that these phenomena are identical with primary recrystallization.

### Activation Energy and Frequency Coefficient

The data secured from isochronal annealing experiments and collected both in Appendix 1 and Figs. 2 and 3 can be used for calculation of two coefficients, namely, the activation energy and the frequency coefficient of primary recrystallization. Since a number of suitably spaced reductions between 5 and 95 pct reduction have been tested, the change of these constants as a function of the degree of cold work ( $z$ ) can also be determined. The calculations are based on the fact that primary recrystallization is an activated process.<sup>12, 18</sup> In the absence of pronounced side phenomena such as strain-age-hardening and excessive crystal growth, primary recrystallization is described by the expression:

$$x = 1 - e^{-c, t, e^{-A/RT}}$$

or

$$\log \frac{1}{1-x} = c, t, e^{-A/RT}$$

In this expression,  $x$  is the fraction of a unit volume of a work-hardened metal sample which has fully recrystallized on subsequent reannealing. Depending on conditions of reannealing, i.e., on temperature of reannealing,  $T^\circ\text{K}$  and the time in hours,  $t$ ,  $x$  may acquire any value between 0 and 1. The expression also contains  $A$ , the activation energy of the recrystallization process,  $R$ , the gas constant, and  $k$ , the frequency coefficient.

For a given metal sample, having the same composition and history, the values  $A$  and  $C$  are constant. To find numerical values of these it is necessary to plot  $\log\log 1/(1-x)$  vs.  $1/T$ . The numerical

values of  $x$  required for this step can be secured from reannealing data such as those collected in Appendix 1, if the properties studied are additive to a degree sufficient for the purpose. The properties studied in the present work are considered as adequately fulfilling this condition. The calculation of the amount of the fully annealed state in partially annealed samples  $x$  has been obtained from the proportion:

$$x = \frac{(P_z - P_a)}{(P_z - P_0)}$$

when using properties which decrease on reannealing, viz., ultimate stress and proof stress from bending. When a property that increases on reannealing is used, such as elongation, both the numerator and the divisor in the proportion are multiplied by  $(-1)$ . In the above proportion,  $P_z$  designates the value of a property found when testing a fully cold-worked sample without any annealing;  $P_x$ , the value of the same property found after annealing for 15 min at temperature  $T^\circ\text{K}$ ; and  $P_0$ , the level of property values found in totally annealed samples.

With the exception of the data for  $z = 21.5$  pct all the data assembled in the Appendix have been used and values of  $\log\log 1/(1-x)$  calculated. These, whether derived from the values of ultimate stress, proof stress, or elongation of a given percentage of reduction of the wire, have been plotted on the same diagram vs. the inverse of the absolute temperature of annealing. The points for each percentage of reduction arranged themselves into straight lines. The spread of points present introduced some uncertainty as to the true position of the straight line. To secure straight lines, the slope of which would yield the value of activation energy  $A$ , five different observers were asked to determine their version of the slopes of the straight line for

Fig. 5—Space diagram showing the agreement between the experimental and calculated values of the ultimate stress of silver cold drawn to the reductions indicated and subsequently annealed for 15 min at the temperatures indicated. Open circles, experimental; filled in circles, calculated.

Fig. 6—Space diagram showing the agreement between the experimental and calculated values of 2 in. elongation of silver cold drawn to the reductions indicated and subsequently annealed for 15 min at the temperatures indicated. Open circles, experimental; filled in circles, calculated.

each system of points. The slopes thus obtained resulted in average values of the activation energies and frequency coefficients of each degree of cold work. A plot of these coefficients vs. the corresponding percentage of reduction is given in Fig. 4. The values for 21 pct reduction have been obtained by interpolation. The differences between the different observers, alone, make these points uncertain to within  $\pm 4000$  cal per mol. It may be seen in Fig. 4 that the activation energy remains constant up to 65 pct of cold work and diminishes steadily for higher percentages of reduction. The constant level of activation energy is approximately at 30,000 cal per mol, a value found previously for copper, nickel, and iron.

The values of the frequency coefficient,  $c$ , are also plotted on Fig. 4. They arrange themselves into a curve which slowly increases up to about 60 pct reduction and subsequently decreases. This decrease is very rapid.

#### Verification of the Treatment Employed

There are two pertinent questions which demand an answer: 1—how accurately do the equations used in the treatment describe the course of reannealing, and 2—how well are the activation energy and the frequency coefficients determined? A positive answer to both questions can be secured by confronting the experimentally found values of three properties studied after 15 min annealing at different temperatures with corresponding values derived by calculation from the equations used. A reasonably good coincidence of calculated and experimental points should constitute a proof that both the equations employed, as well as the constants used, are sound. Too great a difference between the experimental and calculated values would indicate that either the equation or the constants are wrong. An additional investigation would then be necessary to secure an individual answer to the two questions.

The detailed calculations of the  $P_s$  values are omitted here. The steps involved in arriving at the

calculated  $P_s$  values are as follows: 1—substituting into the main equation numerical values of  $A$  and  $c$  found for silver with the percentage of reduction examined, together with numerical values of  $R$  and  $t = 15$  min; 2—finding numerical values of  $x$  from this equation for several assumed values of temperature,  $T$ ; 3—substituting these values of  $x$  into the auxiliary equation,  $x = (P_s - P_s)/(P_s - P_s)$ , together with numerical values of  $P_s$  and  $P_s$ ; and 4—solving this equation for  $P_s$ . The values of ultimate stress, proof stress, and 2 in. elongation thus obtained have been plotted against the assumed temperatures of annealing (filled double circles in Figs. 5, 6, and 7). The experimental data from Appendix 1 have also been plotted on the same diagram (open double circles). As may be seen from these figures, in which all results are collected, the calculated and experimental points lie as closely together as can be hoped for. Because the experimental and calculated curves coincide, a conclusion can be drawn that the equation used truly depicts the course of reannealing of silver, and that the numerical values of the activation energy as well as those of the frequency coefficients have been determined to a satisfactory degree.

#### Discussion

A few remarks concerning the curves of the activation energy and of the frequency coefficient, Fig. 4, are in order. Up to a 60 pct reduction, both these curves behave like similar curves for iron and nickel tested by this method. Here, the activation energy remains almost constant and at the same 30,000 cal level, while the frequency coefficient increases. Such a run of the curves is quite in conformity with the principles of the activation mechanism, though it is not entirely clear why all three metals should require the same activation energy for primary recrystallization.

Above the 60 pct reduction, that is, in the third region of plasticity, both the activation energy and the frequency coefficient of primary recrystalliza-

Fig. 7—Space diagram showing the agreement between the experimental and calculated values of the proof stress from the hardening of silver cold drawn to the reductions indicated and subsequently annealed for 15 min at the temperatures indicated. Open circles, experimental; filled in circles, calculated.

tion of silver diminish. This is unexpected, for, with the lowering of the activation energy, it would be reasonable to expect the frequency coefficient to increase. The verification treatment reveals (see Figs. 5, 6, and 7) approximately the same closeness of experimental and calculated points both below and above the 60 pct reduction. This means that the pairs of the frequency coefficients and activation energies, which determine the result of calculation, are quite accurate throughout the whole range of reduction studied. It appears from the above that the lowering of the activation energy and of the frequency coefficient after 60 pct reduction is real and that it is associated with the differences exhibited by reannealing curves after 60 pct reduction is passed. In the region above 60 pct reduction, the drop in properties extends over a longer interval of temperature; the end of recrystallization ( $T_s$ ) remaining about the same, while the beginning of recrystallization moves rapidly towards room temperature as the percentage of reduction increases, Fig. 1.

The behavior of this kind is no doubt a demonstration of the tendency to self-annealing, to which severely cold-worked silver is known to be prone. The work of Wood<sup>11</sup> reveals that silver, very similar in purity to that used in this work, started to self-anneal when 60 pct reduction was reached.

Thus, the unexpected lowering of the frequency coefficient when the activation energy decreases should be linked with the causes and the mechanism of self-annealing. As our knowledge of self-anneal-

ing is limited, the clarification of the issue raised by this work must be left for future research.

In view of the findings presented in this paper, it appears that the recovery of mechanical properties of cold-worked silver on reannealing is caused by primary recrystallization, that is, principally by conversion of the fully work-hardened state into a fully annealed one, and that this process is somewhat affected by the tendency for self-annealing, which occurs at reductions higher than 60 pct.

# Effect of Rare-Earth Metals On the Properties of Extruded Magnesium

by T. E. Leontis

The specific effect of various rare-earth metals on the room- and elevated-temperature properties of magnesium has been evaluated. Alloys containing didymium exhibit the highest tensile and compressive strengths at room and elevated temperatures. All the rare-earth metals increase the creep resistance of extruded magnesium at temperatures in the range of 400° to 600°F, but the degree of enhancement depends on the temperature and on the concentration of the added metal.

THE effects of rare-earth metals on the properties of sand-cast magnesium were discussed in some detail in earlier paper by the author.<sup>1</sup> The present paper deals with the effect of the same alloying elements on the properties of extruded magnesium. This investigation also had as its aim the development of a wrought alloy having a better combination of room-temperature strength and ductility and elevated-temperature strength and creep resistance than is found in magnesium-Mischmetal-manganese alloys, which have been reported earlier.<sup>2-5</sup> The only known attempt to study wrought magnesium alloys containing pure cerium instead of Mischmetal was made by Mellor and Ridley.<sup>6</sup> They found that in the form of rolled bars there is a definite, optimum cerium content for creep resistance at 200°C and that the creep resistance of these alloys at 200°C is significantly improved by heat treatment at 550° to 580°C.

In the present investigation the compositional variation in mechanical properties of the following alloy systems<sup>7</sup> is presented: 1—magnesium-Mischmetal. 2—magnesium-cerium-free Mischmetal. 3—magnesium-didymium. 4—magnesium-cerium. 5—magnesium-lanthanum. Alloys containing predominantly praseodymium are not included in this series because of the lack of this material.

## Experimental Procedures

The alloying ingredients used in preparing the alloys described herein are the same as those reported in the earlier paper.<sup>1</sup> Cerium-free Mischmetal is the rare-earth mixture remaining when the cerium is removed from Mischmetal, which contains all the rare-earth metals as they occur naturally in monazite sand, the ore from which Mischmetal is produced. Removal of both cerium and lanthanum from Mischmetal leaves what is commonly called "didymium," consisting predominantly of neodymium and praseodymium. Although the composition of the particular batch of each metal used may differ somewhat from the analysis presented previously, these differences are not great enough to warrant repeat-

ing the specific composition of each material. The electrolytic magnesium used as the starting material in these alloys has the same typical analysis as that given in the earlier paper.<sup>1</sup>

The alloys were prepared in small laboratory melts applying all the necessary precautions for alloying rare-earth metals with magnesium described by Marande.<sup>7</sup> Most melts were large enough to cast one 3 in. diam billet 10 in. long. In a few cases, particularly the didymium-containing alloys, the lack of sufficient amounts of the rare-earth metal limited the size of the billet to 6 to 8 in. All billets were scalped to a diameter of 2 15/16 in. and faced to a length of 9 1/4 in. as limited by the size of the extrusion container.

The alloys were extruded into 1/2 in. diam rod on a 500-ton direct-extrusion press using a 3 in. container. The details of the extrusion step are: billet preheat, 925°F (2 hr); container temperature, 900°F; die temperature, 900°F; extrusion speed, 10 ft per min; reduction ratio, 36:1; and percent reduction, 97.3. The lower melting point of alloys containing didymium<sup>1</sup> necessitated reduction of the extrusion speed to 5 ft per min in order to prevent hot shorting during extrusion. Adequate lengths were cropped from both ends of each extruded rod to assure that all the material used for tests was extruded under uniform conditions.

Tensile and compressive properties at room temperature are reported in the several conditions of heat treatment. The ASTM designations are used to distinguish these conditions as follows:

T5—Direct age at 400°F (16 hr)

T4—Heat treat at 950°F (4 hr) for alloys containing didymium

T4—Heat treat at 1050°F (4 hr) for all other alloys

T6—T4 + age at 400°F (16 hr)

The lower heat-treating temperature for alloys containing didymium is necessitated by the lower melting point of these alloys. All heat treatments were conducted in electrically heated, circulating-air furnaces. A protective atmosphere containing 0.5 to 1.0 pct sulphur dioxide was used for the high temperature heat treatments.

Tension and creep specimens 6 1/2 in. long and compression specimens 1 1/2 in. long were cut from the extruded rod. A reduced section of 3/8 in. diam was machined on the tension specimens, whereas on the creep specimens a reduced section of 0.450 in. diam

T. E. LEONTIS, Member AIME, is associated with the Metallurgical Laboratories, The Dow Chemical Co., Midland, Mich.

Discussion on this paper, TP 3154E, may be sent, 2 copies, to AIME by Jan. 1, 1952. Manuscript, April 16, 1951; revision, Aug. 27, 1951. Detroit Meeting, October 1951.

Fig. 1—Tensile yield strength at room temperature.

was used. The ends of the compression specimens were machined square with the cylindrical side, and the tests conducted on the full  $\frac{1}{2}$  in. diam without a reduced section. All tension and compression tests were conducted according to standard ASTM testing procedures. Elongation on the  $\frac{3}{8}$  in. reduced section was measured over a  $1\frac{1}{2}$  in. gage length. Yield strengths were determined by the offset method from autographic stress-strain curves at 0.2 pct deviation from the modulus line. Each result is the average of two tests.

Details of the equipment and methods of creep

testing have been described elsewhere.<sup>2,8</sup> Space does not permit the presentation of the complete creep data either in tabular or graphical form. Instead, the creep characteristics of each alloy are defined by the following three parameters:

- 1—Limiting stress to give 0.1 pct creep extension in 100 hr
- 2—Limiting stress to give 0.2 pct total extension in 100 hr
- 3—Limiting stress to give 0.5 pct total extension in 100 hr

These quantities were derived from log stress vs. log extension plots of the original data as described earlier.<sup>2,8</sup> The total extension figures include the creep extension as well as the initial extension resulting from application of the load. The brevity of these tests prohibits any great significance being ascribed to the measured creep rates, which consequently are not reported in this paper. The method of determining electrical conductivity has been described in an earlier publication.<sup>9</sup>

### Discussion of Results

**Effect of Extrusion Speed and Temperature:** In order to obtain the optimum properties, it is necessary to extrude the alloys under carefully selected conditions. The two most important variables in this process are temperature and speed. Reduction also has some effect on the properties of magnesium extrusions; however, in the case of extruded round rods, the properties are relatively insensitive to reduction over a wide range—as from 16:1 to 144:1. The reduction used in these experiments falls well within this range.

The effect of extrusion speed was determined on an alloy containing 5 to 6 pct Mischmetal + 1.8 pct Mn (according to the ASTM system of designation, this alloy is known as EM62). It was found that in the range of 5 to 25 ft per min, extrusion speed has no significant effect either on the room or elevated-temperature properties of rare-earth containing alloys. Grube, Davis, and Eastwood<sup>3</sup> were able to

show some increase in strength with decreasing speed in the range of 27.3 to 4.11 in. per min.

Considerable work performed in our laboratory has shown that the maximum strength in magnesium-rare-earth alloys in the heat-treated and aged condition (T6) is developed by extruding at 900°F or higher. Results of one such experiment are presented in Table I. Although the lower extrusion temperature produces definitely higher yield strengths in the as-extruded and in the T5 conditions, significantly higher properties are obtained in the T6 condition by extruding at 900°F. Increasing the temperature above 900°F does not produce an increase in strength large enough to warrant use of such higher temperatures with the attendant greater wear on extrusion equipment and dies. The effect of extrusion temperature is more extensively presented by Grube, Davis, and Eastwood.<sup>3</sup>

**Effect of Heat Treatment:** The data included in Table I also show the pronounced beneficial effect that heat treating magnesium-rare-earth alloys has on the elevated-temperature strength and creep resistance. Whereas the alloy extruded at 700°F has the best combination of tensile and compressive properties at room temperature in the T5 condition, much higher strengths are exhibited by the same alloy in the T6 condition at elevated temperature. The superiority of the T6 condition is greater the higher the temperature of test. The comparison of creep properties is even more striking, as shown by the appropriate data in the same table.

Thus, it is apparent that in order to develop the maximum creep resistance and strength at elevated temperature in extruded magnesium-rare-earth alloys, the extrusion must be performed at 900°F or higher and the alloys must be heat treated and aged. Lower heat-treating temperatures produce proportionately lower properties. Increasing the heat-treating time beyond 4 hr does not produce any further advantage.

**Tensile Properties of Mg-Rare-Earth Alloys:** Complete tensile properties at room temperature,

300°, 400°, 500°, and 600°F have been determined on the five magnesium-rare-earth alloy systems as a function of composition. The results are presented graphically in the form of property vs. composition plots in Figs. 1 to 8 inclusive. Because of the small number of compositions investigated, the points have been joined by straight lines.

One of the most significant observations to be made from the room-temperature properties depicted in Figs. 1 to 4 is the marked difference in the degree of age hardening exhibited by the various alloy systems. In the as-extruded and in the heat-treated (T4) conditions, magnesium-lanthanum alloys show a decided superiority over all the other alloy systems, which differ little among themselves. However, magnesium-lanthanum alloys show no age hardening whatsoever, whereas all the other alloys increase in strength upon aging. In general, the degree of aging among the other four alloys increases in the following order: 1—magnesium-cerium. 2—magnesium-Mischmetal. 3—magnesium-cerium-free Mischmetal. 4—magnesium-didymium. This is a direct confirmation of the observations made on the corresponding cast alloys.<sup>1</sup> The result of these marked differences in age hardenability is to give magnesium-didymium alloys the highest strength in the heat-treated and aged condition (T6). In the directly aged state (T5 condition), the full extent of aging is not realized. Thus, magnesium-lanthanum alloys retain their as-extruded superiority in yield strength, but the tensile strength of the magnesium-didymium alloys is significantly higher than all the alloys.

It can be seen from Fig. 4 that the high strengths of the magnesium-lanthanum alloys are associated with relatively low ductility. Magnesium-didymium alloys have, in general, the highest elongation. The ductility of all magnesium-rare-earth alloys goes through a definite maximum at about 1 to 2 pct alloy content. The initial increase in elongation is a result of the marked reduction in grain size effected by the addition of small amounts of rare earths. The elongation decreases with further increases in rare-earth

Fig. 5—Tensile yield strength at elevated temperatures T6 condition.

Fig. 6—Compressive yield strength at elevated temperatures T6 condition.

Fig. 7—Tensile strength at elevated temperatures T6 condition.

content because of the increasing amounts of undissolved intermetallic compounds.

The elevated-temperature tensile and compressive properties of magnesium-rare-earth alloys (Figs. 5 to 8) present a more straightforward picture. At all temperatures investigated in the range of 300° to 600°F, the alloys fall in the following order of decreasing strength: 1—magnesium-didymium. 2—magnesium-cerium-free Mischmetal. 3—magnesium-Mischmetal. 4—magnesium-cerium. 5—magnesium-lanthanum. The spread in the strength properties of the alloys increases with increasing alloy content. The low strength of magnesium-lanthanum alloys is associated with very high elongation. The other magnesium-rare-earth alloys do not show very great differences in ductility at elevated temperatures.

**Creep of Magnesium-Rare-Earth Alloys:** The creep resistance of the various magnesium-rare-earth alloys in the T6 condition at 400°, 500°, and 600°F is shown in Figs. 9, 10, and 11, respectively. The relative effects of the various rare-earth metals on the creep resistance of magnesium depend to a great extent upon the temperature of test and to some extent upon the composition. At 400°F, magnesium-lanthanum alloys are markedly inferior to

Fig. 8—Elongation at elevated temperatures T6 condition.

Fig. 10—100-hr limiting creep stresses at 500°F T6 condition.

all the other alloys and magnesium-didymium alloys have the highest creep limits, particularly at the higher end of the composition range investigated. The creep limits of magnesium-lanthanum alloys at 500° and 600°F vary with composition in a strikingly different manner from those of the other four alloy systems. Whereas the creep limits of the magnesium-lanthanum alloys increase regularly with the composition, those for alloys containing Mischmetal, didymium, cerium-free Mischmetal, and cerium rise to a maximum at about 1 to 2 pct rare-earth content and decrease sharply from this value with increasing alloy content. The result of these compositional trends is that the creep resistance of the magnesium + 5.7 pct La alloy is the highest observed at 600°F. Likewise at 500°F this composition tends to show higher creep resistance than is produced by the same quantities of the other solutes studied. The alloys

Fig. 11—100-hr limiting creep stresses at 600°F T6 condition.

Fig. 12—Electrical conductivity at 95°F.

containing cerium-free Mischmetal exhibit the highest resistance to creep at the higher temperatures over the entire composition range. The decrease in creep resistance of all except the lanthanum-containing alloys may be attributed to a decrease in grain size from about 0.005 in. for the 1 pct alloy content to about 0.002 in. for the 5 pct alloy content. Magnesium-lanthanum alloys, on the other hand, retain a much finer grain size of about 0.0006 to 0.0009 over the composition range of 2.5 to 5.7 pct La as a result of the higher proportion of lanthanum in the form of compound. Perhaps the higher creep resistance of the lanthanum-containing alloys at 600°F results from the combination of fine grain size and a large amount of undissolved compound.

**Effect of Manganese on Magnesium + 5 Pct Rare-Earth Alloys:** In general, the addition of 2 pct Mn to magnesium + 5 pct rare-earth alloys increases

Table III. Limiting Creep Stresses of Magnesium-Rare-Earth-Manganese Alloys

the strength properties by 1000 to 2000 psi at all temperatures (Table II). The room temperature tensile properties of the binary magnesium + 1.85 pct Mn alloy, extruded under the same conditions as the magnesium-rare-earth alloys, are comparable to those of the latter alloys. However, the compressive yield strength of the binary magnesium-manganese alloy is much lower. Magnesium + 1.85 Mn alloy, however, does not exhibit the same degree of temperature resistance that the rare-earth alloys show.

Manganese also effects a definite improvement in the creep resistance of magnesium-rare-earth alloys (Table III). Much the same order of relative creep resistance is maintained among the various magnesium-rare-earth alloys even with the addition of manganese. This is not true at 600°F, where the alloy containing pure cerium has the highest creep limits and the Mischmetal-containing alloy is second. The creep characteristics of magnesium + 1.85 Mn have been determined in various conditions of

heat treatment. Whereas at 400°F this alloy cannot compare with the rare-earth alloys, at 600°F in the heat-treated, quenched, and aged condition, its creep limits are not much lower than those of the magnesium-manganese-Mischmetal alloy. Quenching the magnesium-1.85 Mn alloy from the heat-treating temperature effects a significant improvement in the creep resistance at 600°F. This treatment, however, was not found to have any effect on the tensile properties. Grube, Davis, and Eastwood<sup>8</sup> found the same behavior in this composition. Furthermore, these investigators showed that in alloys containing Mischmetal and manganese, no significant improvement in creep resistance is realized by quenching instead of air cooling from the heat-treating temperature.

**Electrical Conductivity:** The results of conductivity measurements (Fig. 12) show trends similar to those found in the sand-cast alloys. The low solubility of lanthanum in magnesium is again demonstrated by these data. No special significance should be attached to the maxima in the curves for magnesium-lanthanum alloys. Two possible explanations that might be proposed for this phenomena are: 1—differences in impurity content, and 2—differences in degree of preferred orientation.

**Metallography:** Selected micrographs of some of the magnesium-rare-earth alloys are shown in Figs. 13 to 18 inclusive. All the structures were revealed by etching with the standard glycol etchant which contains 75 parts ethylene glycol, 24 parts distilled water, and 1 part concentrated nitric acid. The as-extruded structures are given at a magnification of 100 diam. In alloys containing Mischmetal (Fig. 13) and didymium (Fig. 14), as well as cerium-free Mischmetal and cerium, the compound is present in the form of stringers of discrete particles. The magnesium-lanthanum alloy (Fig. 15), however, reveals many characteristics of the cast structure. The compound is present as clusters of small particles resembling a cast eutectic and in many parts of the structure the compound completely outlines the cast grains. These structural differences in the alloys correlate well with the as-cast microstructure. It was shown in the earlier paper<sup>1</sup> that in alloys containing mixtures of rare-earth metals, the eutectics are highly divorced and thus upon extrusion result in stringers of individual particles. Magnesium-lanthanum and magnesium-cerium alloys, on the other hand, form extremely fine eutectics in the cast state with the divorcement tendency being the least in the magnesium-lanthanum alloys. The extruded magnesium-cerium alloys show a slight indication of the eutectic, as in the magnesium-lanthanum alloys, but the slower freezing rate of a 3-in. diam billet as compared to a cast test bar probably leads to considerable divorcement of the eutectic in the magnesium-cerium alloys.

In Figs. 16, 17, and 18 the microstructures of the magnesium-Mischmetal, magnesium-didymium, and

magnesium-lanthanum alloys in the T6 condition show that the heat treatment results in considerable solution of compound in the two former alloys and in marked coalescence of the undissolved compound in all three alloys. It is clear from these micrographs and from observations on the other alloys that the order of increasing solid solubility in magnesium of these metals is: 1—lanthanum, 2—cerium, 3—Mischmetal, 4—cerium-free Mischmetal, and 5—didymium. These observations agree well with the conductivity measurements, Fig. 12. All the alloys containing about 1 pct rare earths also have significant amounts of undissolved compound except the magnesium + 1.23 pct didymium alloy. The latter has only a trace, indicating that its solid solubility limit in magnesium must be close to this composition.

### Summary

1—Data have been presented to show the specific effects of various rare-earth metals on the room and elevated-temperature properties of extruded magnesium.

2—Alloys may be rated in the following order of decreasing tensile and compressive properties at room and elevated temperatures and creep resistance at 400°F: 1—magnesium-didymium, 2—magnesium-cerium-free Mischmetal, 3—magnesium-Mischmetal, 4—magnesium-cerium, 5—magnesium-lanthanum.

3—Magnesium-didymium alloys do not maintain their superiority in creep resistance over the other alloys at 500° and 600°F. The highest creep resistance over the entire composition range at these temperatures is exhibited by magnesium-cerium-free Mischmetal alloys. High-lanthanum alloys are exceptional in creep resistance at 600°F.

4—It is possible to develop equivalent creep resistance at 400°F with a more favorable combination of strength and ductility at room temperature and higher strength at elevated temperature by using 2 to 3 pct didymium rather than 2 to 5 pct Mischmetal. These effects are illustrated in Table IV.

# Preferred Orientation in Zirconium

by R. K. McGeary and B. Lustman

The textures produced in zirconium by cold and hot rolling, and by recrystallization above and below the transformation temperature were determined. Thermal expansivities were measured in the thickness, transverse, and rolling directions of preferentially oriented zirconium and were correlated with the texture scatter in these directions.

PREVIOUS investigations have indicated that minor differences between hexagonal close-packed metals of similar axial ratio may appear with respect to the textures produced both on cold rolling and on subsequent recrystallization. In the case of magnesium, beryllium, and titanium, metals of axial ratio similar to that of zirconium, the ideal orientations produced by rolling are fundamentally the same, although marked variance is reported in the degree and type of scatter about the mean orientation; in those instances where recrystallization textures were observed, they were reported to be similar to the rolling textures. Measurement of the anisotropy of thermal expansion of both rolled and recrystallized zirconium could not be correlated satisfactorily with the textures reported for the above metals, and therefore a study was made of the preferred orientations produced in zirconium. Reported below are the textures produced in zirconium by cold and hot rolling, and recrystallization above and below the transformation temperature, together with the results of thermal expansion measurements.

## Determination of Preferred Orientation

Two types of zirconium were investigated: 1—"crystal bar" zirconium obtained from the Foote Mineral Co., produced by the thermal decomposition of zirconium tetraiodide, and 2—zirconium ingot obtained from the Bureau of Mines prepared by melting sponge zirconium in a graphite resistor vacuum furnace in a graphite crucible.

The major impurities present in the two materials used are listed in Table I. Several of the pole figures were later checked with 0.03 pct hafnium crystal bar material and the results were identical with those to be shown for the 1.5 pct hafnium material.

The materials were cold rolled to 0.014 in. in thickness as shown in Table II.

Specimens were cut from the 0.014 in. thick rolled sheets and etched to thicknesses of 0.002 to 0.010 in. Such specimens were used for exposures up to a 50° to 60° angle between the beam and plane of the specimen; for higher angles a wire shape, similar to that described by Bakarian,<sup>1</sup> was formed on an end of the original 0.014 in. sheet. A fine-bladed abrasive

cut-off wheel was used to slot the sheet and to form the cylindrical cross-section. The wire shaped ends were then etched to 0.006 to 0.010 in. in diam. Although absorption of X-rays in the wire-shaped specimens does not vary with angle of rotation, the line width around the diffraction rings was not uniform, because the wire was narrower than the X-ray beam, and this condition caused some uncertainty in the estimation of azimuthal intensities. Furthermore, scanning was not practicable with this type of specimen so that spottiness of the rings due to large grain size was excessive for specimens which had been heated above about 650°C. Nevertheless, satisfactory information could be obtained for high angle exposures from the negatives by the use of both types of specimens.

Transmission Laue photograms were taken using unfiltered molybdenum radiation (47.5 kv, 18 ma) and a 0.025 in. pinhole. With the film 8 cm from a 0.005 in. thick specimen exposures of about 30 min were adequate. For specimens with a coarse grain size, a device that scanned about 0.15 sq in. of sheet surface was used.

An attempt was made to plot the pole figures by use of an X-ray spectrometer as described by Norton.<sup>2</sup> However, for the particular technique used, the intensity variations obtained were not considered definite enough to give reliable results, especially for the large grained recrystallized and transformed specimens. This method was therefore abandoned in favor of the standard photographic method.

Nine exposures were taken of each specimen: seven exposures with the beam perpendicular to the rolling direction and at 0°, 10°, 20°, 35°, 50°, 65°, and 80° to the transverse direction, and two exposures with the beam perpendicular to the transverse direction and at 60° and 80° to the rolling direction. Additional exposures were then made where necessary. The intensity variations of the diffraction rings were estimated by eye. It was usually possible to estimate 3 degrees of intensity from the photograms but in some cases 2, 4, or 5 degrees were estimated.

## Experimental Results

The preferred orientation was determined for the following treatments: 1—cold-rolled, 2—low temperature rolled, 3—cold-rolled surface layer, 4—cross-rolled, 5—hot-rolled, 6—recrystallized below the transformation temperature, and 7—recrystallized above the transformation temperature.

1—Cold-Rolled Textures: The slip plane in hexag-

R. K. McGEARY and B. LUSTMAN, Member AIME, are associated with the Atomic Power Div., Westinghouse Electric Corp., Pittsburgh.

Discussion on this paper, TP 3160E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, May 3, 1951. New York Meeting, February 1952.

onal close-packed metals is the basal {0001} plane. During cold rolling this plane would be expected to rotate into the plane of the sheet by slip along the  $\langle 11\bar{2}0 \rangle$  directions. With such a slip mechanism the principal ideal orientation produced by cold rolling would be expected to consist of basal planes parallel to the rolling plane and either  $\langle 11\bar{2}0 \rangle$  or  $\langle 10\bar{1}0 \rangle$  directions parallel to the rolling direction.

For magnesium with an axial ratio ( $c/a = 1.624$ ) similar to that of zirconium (1.589), Caglioti and Sachs<sup>8</sup> found the {0001},  $\langle 11\bar{2}0 \rangle$  orientation, with the scatter greater in the rolling direction than in the transverse direction. Bakarian,<sup>1</sup> using purer magnesium than Caglioti and Sachs, found the same basal plane orientation but no directional orientation of the digonal axes. He showed also that the rolling texture is affected by the presence of certain impurities; 0.2 pct Ca caused a splitting of the central maximum area of the pole figure.

The basal plane pole figure of cobalt by Wasserman<sup>4</sup> indicates a splitting of the maximum area but no directionality of scatter.

Smigelskas and Barrett<sup>5</sup> observed a {0001},  $\langle 10\bar{1}0 \rangle$  orientation in the case of beryllium; this is the first observation that the  $\langle 10\bar{1}0 \rangle$  direction may lie in the rolling direction for close-packed hexagonal metals. Considerably more scatter in the transverse than in the rolling direction is apparent.

The pole figures of Clark<sup>6</sup> for cold-rolled titanium indicate that the hexagonal axis is inclined in the transverse direction about  $30^\circ$  from the rolling plane with the  $\langle 10\bar{1}0 \rangle$  direction in the rolling direction.

Burgers and Jacobs<sup>7</sup> pole figures of cold-rolled zirconium show, as do those of beryllium, the major scatter to be in the transverse direction. However, their pole figure of the {10 $\bar{1}$ 0} planes indicates a tendency for the  $\langle 11\bar{2}0 \rangle$  direction to lie in the rolling direction.

The pole figures of cold-rolled Bureau of Mines zirconium obtained in the present investigation for the three principal planes, {0002}, {10 $\bar{1}$ 0}, and {10 $\bar{1}$ 1}, are shown in Fig. 1a, b, and c. The pole figures of crystal bar zirconium are fundamentally the same as those of Bureau of Mines zirconium but with less scatter in the transverse direction. The average orientation best describing the maximum intensity areas, shown by the double circle points in Fig. 1, is that shown in the schematic drawing of Fig. 7a, which represents the basal planes parallel to the rolling direction but inclined from the rolling plane about  $30^\circ$  in the transverse direction, and with a  $\langle 10\bar{1}0 \rangle$  direction in the rolling direction. This orientation is most readily appreciated by consideration of the prism-plane {10 $\bar{1}$ 0}, and pyramidal-plane {10 $\bar{1}$ 1} pole figures. The diffraction photograms of Fig. 8a and b also indicate the  $30^\circ$  transverse tilt of the c-axis: four maxima intensity arcs appear at the 7, 8, 10, and 11 o'clock positions of the outer {10 $\bar{1}$ 1} ring of Fig. 8a, while maxima intensity arcs appear only at the 7 and 11 o'clock positions in Fig. 8b where the specimen was rotated  $20^\circ$  about the rolling direction.

2—*Low Temperature Rolling*: It was thought that the slip mechanism of zirconium might change with temperature as is observed in the case of magnesium, and that the change might be reflected in the rolling texture. Therefore, a piece of crystal bar

Table I. Composition of Materials Used

| Impurity       | In Crystal Bar, Pct | In Melted Bureau of Mines Sponge, Pct |
|----------------|---------------------|---------------------------------------|
| Hf             | 1.5                 | 1.5                                   |
| C              | 0.02                | 0.09                                  |
| O <sub>2</sub> | 0.02                | 0.08                                  |
| Fe             | 0.01-0.05           | 0.14                                  |

zirconium was rolled 95 pct at liquid nitrogen temperature. The texture of this material is in all respects similar to that of the crystal bar rolled at room temperature.

3—*Surface-Layer Texture*: It is often the case in wire drawing or cold rolling that the textures observed on the surface are different from those in the body of the metal because of inhomogeneity of the deformation process. The surface texture of Bureau of Mines zirconium was determined on a specimen coated on one side with wax and etched from 0.014 to 0.002 in. in thickness. The pole figures for this specimen did not reveal a new orientation but only a slight sharpening of the cold-rolling texture.

4—*Cross-Rolled Texture*: A square specimen of Bureau of Mines zirconium, which had previously been hot rolled, was cold rolled 90 pct by rotating the square  $90^\circ$  after each pass through the rolls. Each reduction was about 3 pct of the total reduction. The pole figures of Fig. 2 indicate that scatter in the transverse direction has been eliminated and that the cross rolling has resulted in a texture consisting of a basal plane parallel to the rolling plane, a  $\langle 10\bar{1}0 \rangle$  direction parallel to one rolling direction, and a  $\langle 11\bar{2}0 \rangle$  direction parallel to the other rolling direction. It would hardly be expected that such an orientation would be stable on cross rolling, but it would rather be expected that a double orientation with some  $\langle 10\bar{1}0 \rangle$  directions parallel to each rolling direction would be observed. However, if the rolling process is idealized as a combination of tension in the rolling direction and compression in the normal direction, and if a  $\langle 10\bar{1}0 \rangle$  direction were stabilized in the one rolling direction by duplex slip along  $\langle 11\bar{2}0 \rangle$  directions, then, in the direction transverse to this, the  $\langle 11\bar{2}0 \rangle$  direction would similarly be stabilized by duplex slip. To test the effect of orientation prior to cross rolling, a slab of as-cast ingot zirconium, which would not be expected to show any prior orientation, was cross rolled, and also exhibited a  $\langle 10\bar{1}0 \rangle$  direction parallel to the one rolling direction and a  $\langle 11\bar{2}0 \rangle$  direction parallel to the other.

5—*Hot-Rolled Texture*: With the exception of beryllium,<sup>5</sup> there is no information on the orientations produced by hot rolling hexagonal close-packed metals. For this metal the type of orientation for rolling temperatures as high as  $800^\circ\text{C}$  does not change.

Table II. Rolling Schedule

| Material        | Type Rolling | Rolling Temperature | Reduction in Thickness, Pct |
|-----------------|--------------|---------------------|-----------------------------|
| Crystal bar     | Straight     | Room temperature    | 95                          |
| Bureau of Mines | Straight     | Room temperature    | 96                          |
| Bureau of Mines | Straight     | $850^\circ\text{C}$ | 92                          |
| Bureau of Mines | Cross        | Room temperature    | 90                          |

Hot rolling was performed on a specimen of Bureau of Mines zirconium plate, which was placed in a close-fitting steel jacket with  $\frac{3}{8}$  in. thick walls, all the seams of which were then welded gas tight. The jacket helped in maintaining the proper temperature of the sample and also in protecting it from oxidation. The total deformation at a temperature of 825° to 850°C was about 92 pct reduction in thickness. The pole figures for this sample, Fig. 3, indicate that the texture is essentially the same as the cold-rolled texture but has much more scatter in the transverse direction.

6—*Recrystallization Textures:* The textures that result when cubic metals are rolled and recrystallized are greatly varied and at present cannot be correlated successfully with any general theory. For

these metals the recrystallization textures may be the same as, or may be different from, the deformation texture, or no preferred orientation may result on recrystallization. For hexagonal close-packed metals there has been very little work done on rolling-recrystallization textures or the factors influencing the textures. Zinc and magnesium were found to retain their rolling textures at recrystallization temperatures up to the highest temperatures investigated, 400° and 600°F respectively.<sup>5</sup> The 700°C recrystallization textures of beryllium were also found to be the same as the deformation textures.<sup>5</sup> The basal plane pole figure of Clark<sup>6</sup> for titanium indicates that the recrystallization texture is the same (differing in degree) as the cold-rolled texture. However, a comparison of his photograms for the

Fig. 4—Pole figures for cold rolled and recrystallized (650°C) Bureau of Mines zirconium.

○ indicates {0002} rotated 30° about rolling direction.

{10 $\bar{1}$ 0} and {10 $\bar{1}$ 1} rings with the pole figures and photograms obtained in the present case for zirconium indicates that a rotation of the digonal axes about the hexagonal axis has taken place for titanium. Zirconium will be shown to undergo a 30° rotation of this type when recrystallized.

a—*Cold-Rolled Recrystallization Textures*: Specimens of the 0.014 in. thick cold-rolled sheet zirconium were recrystallized at 650°C. The specimens were sealed in evacuated glass tubes and were put into a hot furnace for 5 min (recrystallization was found to be complete in this time). The recrystallization pole figures for Bureau of Mines zirconium are shown in Fig. 4. The pole figures for recrystallized crystal bar are almost identical to those shown for the Bureau of Mines zirconium. A well-defined tex-

Fig. 6—Pole figures for Bureau of Mines zirconium heated above transformation temperature.

Points indicate calculated pole positions for Burgers' transformation mechanism from an ideal recrystallization orientation. Maximum intensity areas marked M.

ture fundamentally different from the rolling texture was observed. A schematic drawing of the average orientation best explaining the maxima areas of the pole figures is shown in Fig. 7b. The basal planes are inclined to the plane of the sheet at an angle of about 30° in the transverse direction and the <11 $\bar{2}$ 0> direction is parallel to the rolling direction.

Pole figures were plotted for a recrystallized sample which was later found to have been overheated. The heating temperature was below the transformation temperature (862°C), since there was no metallographic evidence of a transformation structure, and was estimated to lie between 800° and 862°C. The pole figures of this specimen were very similar to those of the specimen recrystallized at 650°C, so

the recrystallization texture apparently does not vary in this temperature range.

The average orientation described above may also be considered as a twinned orientation with a  $\{10\bar{1}1\}$  first-order pyramidal twinning plane perpendicular to the rolled sheet and parallel to the rolling direction. The usual twinning planes for close-packed hexagonal metals are the  $\{10\bar{1}2\}$  second-order pyramidal planes. No metallographic evidence of twinning could be found in recrystallized zirconium.

Burgers and Jacobs<sup>7</sup> found the  $\langle 11\bar{2}0 \rangle$  direction parallel to the rolling direction and the basal plane parallel to the rolling plane, while in a later work Burgers, Fast, and Jacobs reported the following ideal fiber textures for zirconium wire:

Cold drawn wire— $\langle 10\bar{1}0 \rangle$  direction parallel to wire axis

Recrystallized wire— $\langle 11\bar{2}0 \rangle$  direction parallel to wire axis

If a reasonable correspondence is assumed between the wire axis and the rolling direction of sheet material, the observations for wire coincide with the present observations for rolled zirconium. It is readily apparent that the rotation of axes described above does occur if a comparison of the innermost  $\{10\bar{1}0\}$  rings of Fig. 8a and c is made. The former figure, a photogram made with the X-ray beam perpendicular to the plane of the cold-rolled sheet, shows maxima in the 6 and 12 o'clock positions, indicating a  $\langle 10\bar{1}0 \rangle$  direction parallel to the rolling direction, while the latter figure, a similar photogram of the recrystallized sheet, shows maxima at the 5, 7, 11, and 1 o'clock positions, indicating a  $\langle 11\bar{2}0 \rangle$  direction parallel to the rolling direction.

For rolled zirconium, the  $\langle 10\bar{1}0 \rangle$  direction was always found to be parallel to the rolling direction. With flow parallel to the rolling direction by duplex slip on basal planes in  $\langle 11\bar{2}0 \rangle$  directions, it would be expected that either a  $\langle 10\bar{1}0 \rangle$  or  $\langle 11\bar{2}0 \rangle$  direction would lie parallel to the rolling direction. Having once established either direction parallel to the rolling direction it would seem impossible to change

it by further working. To find if the preferred  $\langle 11\bar{2}0 \rangle$  direction parallel to the rolling direction observed in the case of recrystallized zirconium could be shifted by further working, the following experiments were performed. The original cold-rolled crystal bar zirconium was recrystallized to place a  $\langle 11\bar{2}0 \rangle$  direction parallel to the rolling direction as shown in the photogram of Fig. 9c. The specimen was then cold rolled an additional 86 pct and the photogram of Fig. 9d taken. It may be noted that once more the  $\langle 10\bar{1}0 \rangle$  direction is parallel to the rolling direction. Subsequent recrystallization again caused a rotation of the  $\langle 11\bar{2}0 \rangle$  into the rolling direction. These direction changes correspond to a  $30^\circ$  rotation about the hexagonal axis. It is interesting to point out the similarity of the above results to those of Beck, Sperry, and Hu<sup>8</sup> who found the maximum rate of growth in the case of recrystallization of aluminum to be at orientations corresponding to a  $30^\circ$  to  $45^\circ$  rotation about a  $\langle 111 \rangle$  axis with respect to the original orientation.

b—*Cross-Rolled Recrystallization Texture*: It was shown in Section 3 and Fig. 7c that the cross-rolled deformation texture had the following ideal orientations: the basal plane parallel to the rolling plane, a  $\langle 10\bar{1}0 \rangle$  direction parallel to one rolling direction, and a  $\langle 11\bar{2}0 \rangle$  direction parallel to the other rolling direction. The pole figures of Fig. 5 showing the recrystallization texture of this specimen indicate a new orientation, shown in the schematic drawing of Fig. 7d: the basal plane is parallel to the rolling plane (as in the deformation orientation) but a  $\langle 11\bar{2}0 \rangle$  direction is oriented parallel to the rolling direction which in the rolled condition was parallel to a  $\langle 10\bar{1}0 \rangle$  direction, and a  $\langle 10\bar{1}0 \rangle$  direction is oriented parallel to the other rolling direction which showed a  $\langle 11\bar{2}0 \rangle$  direction in the rolled condition. This change corresponds to a  $30^\circ$  rotation about the hexagonal axis.

7—*Texture after Heating above the Transformation Temperature*: The allotropic transformation temperature of zirconium has been established as  $862^\circ \pm 5^\circ\text{C}$  by dilatometric and thermal analysis.<sup>10</sup> Above this temperature zirconium is body-centered cubic and below it, hexagonal close-packed. Burg-

ers,<sup>11</sup> by X-ray analysis of selected portions of crystal bar zirconium which were single crystals of the cubic modification at the deposition temperature, found the following orientation relationships between the hexagonal close-packed and the body-centered cubic modifications:

BCC  $\beta$  Zr above 862°C      CPH  $\alpha$  Zr below 862°C  
{110} planes parallel to {0001} planes  
<111> directions parallel to <1120> directions

There are six {110} planes and two <111> directions in each of the planes, hence 12 orientations of  $\alpha$  may result from a single  $\beta$  orientation.

With the electron microscope, Burgers and Van Amstel<sup>12</sup> observed that the lamellar crystallites of hexagonal close-packed zirconium form by a crystallographically reversible type of transition, and that nucleation and growth apparently do not take place in the same sense that they occur in diffusion-type phase transformation processes. Observation at high temperature of certain  $\beta$  zirconium grains revealed that the grains retained their shape on transformation to  $\alpha$  and then back again to  $\beta$  zirconium, and that after several transformations the  $\alpha$  lamellae appear in the same positions with respect to the original  $\beta$  grains that they had previously occupied.

These observations indicate that the orientation existing in recrystallized zirconium should be replaced by a new orientation when heated above the transformation temperature, and that this orientation should not be destroyed by repeated heating above and cooling below the transformation temperature. On heating above the transformation temperature the {110} $_{\beta}$  planes should form parallel to {0001} $_{\alpha}$  planes and a <111> $_{\beta}$  direction parallel to a <1120> $_{\alpha}$  direction. On retransformation of the  $\beta$  to  $\alpha$ , the old as well as entirely new orientations should appear since there are six {110} $_{\beta}$  planes and two <111> $_{\beta}$  directions parallel to which the  $\alpha$  crystallites may form. Finally, on continued heating and cooling through the transformation temperature no new orientations should appear.

a—*Transformation Texture Arising from Recrystallization Texture*: A specimen of cold-rolled Bureau of Mines zirconium was sealed in an evacuated silica capsule and heated for 1 min at 980°C and then air cooled. Diffraction photograms showing the new positions of the basal planes (compare with recrystallization photogram, Fig. 8c) are shown in Fig. 9a and b. In Fig. 6 the pole figures for the three principal planes are shown with the addition of the positions of the poles that may arise from the ideal orientation by applying Burgers' transformation mechanism.

Fig. 7 — Representation of ideal preferred orientation with respect to the rolled sheet (cross-hatched plane is in rolling plane) after: a—cold-rolling, b—recrystallization after cold-rolling, c—cross-rolling, d—recrystallization after cross-rolling.

The areas marked M are the maximum intensity areas which would ordinarily be shown as the closest cross-hatched areas, and all other areas are of lesser intensity. The agreement is seen to be good when the following difficulties encountered in interpreting this set of photograms are considered:

1. The transformation orientation seems inherently possessed of more scatter than the recrystallization orientation.
2. The rings are spotty due to a much larger grain size, a condition which was not overcome by the integrating method employed.
3. There are many more orientations with consequent overlapping of scatter regions. For this reason the intensity regions of the {1010} plane pole figure of Fig. 6b are shown by dotted lines. The photograms showed very little difference in intensity around the {1010} plane rings (cf. Fig. 9a).

b—*Retention of New Texture Despite Repeated Transformation*: It has been shown that no change

of the transformation texture would be expected on cycling through the transformation range except such due to transformation strains and consequent noncoherent recrystallization. If, however, the mechanism were not exactly that described above but close to it, then repeated transformations would be expected to magnify the difference so that eventually a somewhat different texture or complete randomness might result. A duplicate of the specimen of Section 7a was heated eight times for a minute above the transformation temperature and water quenched after each heating. The photogram of Fig. 9b indicates that the orientation of this coarse grained specimen is entirely similar to that of the specimen of Fig. 9a which was transformed only once.

#### Anisotropy of Thermal Expansion

The available data on the expansivity of zirconium are listed in Table III. Depending on the treatment received by the material, and hence the differences in texture so produced, expansivities in the rolling direction ranging from about 4 to 6.5 microin. per in. per °C have been reported. The observed variation of expansivity with deformation and annealing treatment in Table III cannot be correlated with the X-ray results of Shinoda<sup>23</sup> who, in the temperature range 0° to 100°C, reported values of ex-

pansivity of 2.5 and 14.3 microin. per. in. parallel to the *c* and *a* axes respectively; a redetermination by X-ray methods of the expansivity revealed values of 10.3 and 4.5 microin. per in. respectively.<sup>24</sup> The correlation of the experimentally observed expansivity anisotropy with the textures described in previous sections and with values derived from X-ray observations will be discussed below.

#### Experimental Technique

Expansivity was measured in the rolling, transverse, and thickness directions of rolled sheet. Most of the measurements were made by means of a quartz differential dilatometer; the dilatation strain was measured by an unbonded strain gage of about 3 microin. sensitivity. Specimens 0.3 to 0.4 in. in length were used; measurements were made in the thickness directions of rolled sheet by stacking several polished specimens to the proper depth. The specimens were heated at constant rates of 2° to 12°C per min and dilatation measurements made continuously. Results were checked in the case of a cross-rolled specimen by means of a high temperature interferometer dilatometer and were found to agree with those obtained from the differential dilatometer to within the estimated limit of accuracy,  $\pm 0.4 \times 10^{-6}$  in. per in. per °C for a 0.3-in. length of specimen. Tabulated in Table IV are the results of expansivity

Fig. 9—Laue transmission photographs of zirconium.

measurements made on sheet with various rolling and annealing treatments.

#### Experimental Results

It is apparent that a qualitative correlation is possible between the values of expansivity listed in Table IV and the pole figures appropriate for each deformation and annealing treatment if the X-ray values of  $10.3 \times 10^{-6}$  per °C parallel to  $c$  axes and  $4.5 \times 10^{-6}$  per °C parallel to  $a$  axes are assumed for the expansivities of the unit cell axes. Thus the cross-rolled sheet, the texture of which consists of  $c$  axes scattered uniformly about the normal to the sheet direction, shows equal expansivities in the rolling and transverse directions and maximum expansivity in the thickness direction. In the case of hot-rolled and recrystallized zirconium the scatter of the  $c$  axes is principally in the transverse direction; thus the expansivity here decreases in the order thickness, transverse, and rolling direction. The transformed material exhibits  $c$  axes scattered fairly uniformly over the entire projection and correspondingly the expansivity is fairly uniform in the three sheet directions.

Expansivity measurements made on cold-rolled material showed abnormally low expansivity in the transverse direction and high expansivity in the thickness direction, considering the type of scatter for this texture. Presumably these values are abnormal because of stresses in the specimens, since on prior stress-relieving at 325°C more reasonable values for expansivity were obtained.

A more quantitative correlation of texture and expansivity is possible in the case of recrystallized sheet in which the unit cell is inclined with its  $c$  axis about 30° from the normal direction in the transverse direction. Scatter about this average orientation is fairly isotropic. The expansivities in the three sheet directions may be calculated from the formula:

$$\alpha_{th, tr, r} = (\alpha_c - \alpha_a) \cos^2 \phi_{th, tr, r} + \alpha_a$$

where  $\alpha_c = 10.4 \pm 0.5 \times 10^{-6}$  per °C  
( $c$  expansivity, Table IV)

$$\alpha_a = 4.5 \pm 0.5 \times 10^{-6} \text{ per } ^\circ\text{C}$$

( $a$  expansivity, Table IV)

$$\phi_{th, tr, r} = \text{angle between thickness (th), transverse (tr), or rolling (r) direction and mean orientation of } c \text{ axis.}$$

Fig. 10—Expansivity of recrystallized zirconium sheet.

The experimental and calculated expansivities for recrystallized zirconium are shown in Table V.

The uniform scatter for this texture would be expected to increase the experimental rolling direction measurement and decrease the other two measurements. Since the scatter areas of the pole figures are not quantitative no attempt was made to reconcile their resolved contributions. The variations of expansivity with temperature in the three principal sheet directions of cold-rolled and recrystallized (600°C) Bureau of Mines zirconium are shown in Fig. 10.

### Summary

1—X-ray diffraction methods were used to determine the preferred orientations of crystal bar and Bureau of Mines zirconium which were subjected to several different rolling and heating treatments. The data were presented as pole figures.

2—The cold-rolling texture indicated an average orientation that can be described as having the basal planes, {0001}, parallel to the rolling direction, but inclined from the rolling plane of the sheet about 30° in the transverse direction, with a  $\langle 10\bar{1}0 \rangle$  direction in the rolling direction.

3—The recrystallization texture was different from the cold-rolling texture. The average position of the basal planes was the same as for the cold-rolling texture but a  $\langle 11\bar{2}0 \rangle$  direction was in the rolling direction.

Table V. Linear Expansion Coefficients of Recrystallized Zr ( $\times 10^{-6}$  per °C)

|              | Thick-<br>ness Di-<br>rection | Trans-<br>verse Di-<br>rection | Roll-<br>ing Di-<br>rection | Calcu-<br>lated<br>Volume<br>Coeffi-<br>cient |
|--------------|-------------------------------|--------------------------------|-----------------------------|-----------------------------------------------|
| Experimental | $8.6 \pm 0.4$                 | $6.3 \pm 0.4$                  | $5.5 \pm 0.4$               | $20.4 \pm 1.2$                                |
| Calculated   | $8.9 \pm 0.5$                 | $7.3 \pm 0.5$                  | $4.5 \pm 0.5$               | $20.7 \pm 1.5$                                |

4—The hot-rolling texture was similar to the cold-rolling texture but with more scatter, especially in the transverse direction.

5—A specimen cross rolled at room temperature had a sharp texture with the basal planes parallel to the rolling plane and with the  $\langle 10\bar{1}0 \rangle$  direction in one rolling direction and the  $\langle 11\bar{2}0 \rangle$  direction in the other rolling direction.

6—The recrystallization texture of the cross-rolled zirconium showed the same basal plane orientation as the rolled material, but the  $\langle 11\bar{2}0 \rangle$  direction was in the  $\langle 10\bar{1}0 \rangle$  rolling direction and the  $\langle 10\bar{1}0 \rangle$  direction was in the  $\langle 11\bar{2}0 \rangle$  rolling direction.

7—The texture of surface layers of cold-rolled zirconium was found not to differ fundamentally from that of the interior of the metal.

8—Experimental evidence that the transformation mechanism of  $\beta$  body-centered cubic and hexagonal close-packed  $\alpha$  zirconium is of a crystallographically reversible nature was presented. The transformation texture indicates that the orientation relationship is the same as that reported by Burgers, namely  $\{0001\}_\alpha \parallel \{110\}_\beta, \langle 11\bar{2}0 \rangle_\alpha \parallel \langle 111 \rangle_\beta$ .

9—By X-ray diffraction the thermal expansivity of zirconium in the c-axis direction was found to be  $10.3 \pm 0.5 \times 10^{-6}$  per °C and  $4.5 \pm 0.5 \times 10^{-6}$  per °C in the a-axis direction. The thermal expansivities were measured in the thickness, transverse, and rolling directions of all sheet materials whose textures were determined, and the magnitude of expansion was found to be proportional to the degree of scatter in the three measured directions.

### Acknowledgment

The work described in this paper was done under Atomic Energy Commission Contract AT-11-GEN-14. The authors gratefully acknowledge the expansivity data submitted to them by D. M. Wroughton and G. F. Mechlin, of the Westinghouse Atomic Power Div., and Howard Scott and William Mohr, of the Westinghouse Research Laboratories.

# Grain-Growth and Recrystallization

## Characteristics of Zirconium

by F. J. Dunkerley, F. Pledger, V. Damiano, and J. Fulton

Grain-growth and recrystallization characteristics of a commercially pure zirconium prepared by the iodide process are reported. Grain growth from 640° to 800°C was continuous once initiated and obeyed  $D = kt^n$ . Recrystallization of zirconium occurred at temperatures of 450° to 550°C after deformations of 20 and 50 pct. Hardening from partially soluble inclusions prevented determination of the absolute rates of recrystallization, but the relative rates of recrystallization obtained are useful as a guide in fabrication practice.

**B**ASIC information needed as a guide in the hot and cold working and annealing of metals includes recrystallization and grain-growth data. A search of the literature revealed no such information for pure zirconium. This is a report of practical grain-growth and recrystallization results obtained for a commercial grade of pure zirconium on a project sponsored by the Office of Naval Research. In this work, isothermal grain-growth curves were obtained at five temperatures from 640° to 800°C inclusively; while recrystallization curves have been determined at 450°, 500°, and 550°C for the metal at the deformation levels of 20 and 50 pct. In addition to the usual variables of temperature, time, and deformation, distribution of the second phase found in all commercial grades of iodide zirconium is also treated as an important factor in these grain-growth and recrystallization studies.

Discussion on this paper, TP 3144E, may be sent, 2 copies, to AIME by Jan. 1, 1952. Manuscript, Oct. 16, 1950; revision, June 21, 1951. St. Louis Meeting, February 1951.

In conducting this work, two properties of zirconium were particularly pertinent in dictating experimental conditions. First, since zirconium undergoes a transformation from the  $\alpha$  close-packed hexagonal form to the  $\beta$  body-centered cubic form at 862°C, no recrystallization or grain-growth studies were made above 800°C. Second, because dissolved gases (oxygen, nitrogen and/or hydrogen) increase the hardness and lower the ductility of the solid metal, all annealing treatments in this investigation were carried out in vacuum or in a helium atmosphere.

### Materials and Methods

The zirconium used in this investigation was prepared by the Foote Mineral Co. by deposition from its iodide. A spectrochemical analysis of the metal showed the following composition in weight pct: Hf, 2.1; Mg, 0.012; Fe, 0.035; Si, 0.095; Ti, 0.023; Al, 0.037; Mo, trace; Ni, trace; Cr, trace; Ca, 0.006.

Conventional metallographic procedures involving hand polishing on wet metallographic papers, followed by final polishing on fine, levigated alumina on gamal cloth and a medium speed wheel were used throughout this investigation. Grain boundaries were revealed with modified Tucker's etch containing 20 parts glycerine, 2 parts hydrofluoric acid, and one part nitric acid.

*Grain-Growth Procedure:* Three lots of zirconium, designated here as series A, B, and C were prepared for the grain-growth studies as follows:

Series A was prepared by cold swaging the ½ in. as-deposited rod to a 3/16 in. final diameter, followed

a.  $\alpha_a$  structure heated at 950° for 24 hr and air-cooled.

b.  $\alpha_b$  structure heated at 800° for 72 hr and furnace-cooled.

Fig. 1—Microstructures of deposited zirconium, swaged and heat treated. Etched with 10 pct HF in glycerine. X250.

by annealing for 20 hr at 600°C in an evacuated quartz tube for complete recrystallization. The initial grain size thus developed in the A specimens was 0.009 mm average diameter. These specimens 1/2 in. long were then sealed in vacuum in quartz tubing and heated for times varying from 1/2 to 100 hr at the temperatures 640°, 680°, 720°, 760°, and 800°C for grain-growth studies. Series B was prepared by sheathing a small section of rod with an iron pipe, hot rolling at 700°C to a 1/4 in. rod and finally cold swaging to a 3/16 in. diam rod. This stock was then heated to 800°C for 1 1/2 hr to develop a grain size of 0.024 mm. Series C was prepared by hot rolling as in the case of the B series and then annealing at 800°C to develop a grain size of 0.023 mm. The usual vacuum-annealing technique was then followed in carrying out grain-growth studies on lots B and C at the temperature levels of 640°, 720°, and 800°C. Temperatures were measured with a calibrated chromel-alumel thermocouple and were always maintained within  $\pm 1.5^\circ\text{C}$  of the values reported.

Sections both transverse and longitudinal to the swaging and/or rolling direction were examined and the grain diameters reported are the averages of those on both sections. The usual metallographic grain counting technique was used except paper negatives were made on Kodabromide enlarging paper to facilitate the grain-size measurements. Four to six areas, each containing at least 100 grains, were obtained for each specimen. Grain diameters were calculated from the formula:

$$D = \frac{1.075}{M} \sqrt{\frac{A}{n}}$$

where  $D$  is the average grain diameter in mm;  $A$ , the area of the field in sq mm;  $n$ , the total number of grains; and  $M$ , the magnification. In deriving this formula, it was assumed that all grains were regular hexagons and  $D$  was equal to the distance between opposite flats of the hexagon.

**Recrystallization Procedure:** In order to include distribution of the second phase as a variable, the stock metal was prepared and heat treated in the following manner:

The 1/2 in. deposited rod was cold swaged to 1/4 in. diam and a suitable length was sealed in an evacuated quartz tube, heated at 950°C for 24 hr, and air cooled. This produced the structure shown in Fig. 1a, designated hereafter as  $\alpha_a$ . The second phase occurs here as coarse lamellar platelets with different orientations in adjacent grains. The second section of 1/4 in. rod was heated at 800°C for 72 hr and furnace cooled.

Here the second phase is agglomerated in the grain boundaries, as shown in Fig. 1b. Material treated in this way will be designated hereafter as  $\alpha_b$ . Portions of the annealed rods were then cold worked on a 5x8 in. flat-roll mill to 20 and 50 pct reductions in cross-sectional area, light passes of about 0.005 in. each being taken to achieve as nearly uniform deformation as possible. The change in length in cold rolling was used in the usual way as the criterion of reduction in area.

Specimens of each structure and reduction were annealed isothermally in vacuum at 450°, 500°, and 550°C. A muffle furnace was used to anneal specimens for 1/2 hr or longer, while a constant temperature bath was used when the time of annealing was less than 1/2 hr. Temperature gradients in the muffle furnace were eliminated by placing the tubes in a cavity in the center of a high heat capacity steel bar, 2 1/2 in. in diam x 7 in. in length. Specimens were admitted to the furnace or salt bath at temperature in order to obtain maximum heating rate and to assure accurate time control. Time to attain temperature was experimentally found to be 2 min in the furnace and 3 sec in the salt bath, and this was subtracted from the total time of annealing in each case. The short-time specimens were heated by direct immersion in the salt bath followed by air cooling. The long-time specimens which were sealed in evacuated quartz tubes were air cooled.

Hardness measurements or the rate of softening as a result of recrystallization anneals were used as the major tool for following the progress of recrystallization, since the more classical metallographic<sup>1</sup> technique was difficult to carry out on zirconium. The annealed specimens were thus mounted in bakelite and finish-ground on 600 grit wet metallographic paper in preparation for hardness measurements. The Rockwell Superficial 30-T scale was chosen for hardness measurements because this gave the sensitivity required. An average of seven indentations on specimens reduced 20 pct, and five indentations on those reduced 50 pct were taken as the hardness of the annealed material. A limited number of metallographic determinations of percentage recrystallized were made as checks on the softening data.

## Results and Discussion

**Grain Growth:** Although not all pure metals exhibit a straight line relationship when  $\log D$  is plotted vs.  $\log t$ , as suggested by the equation<sup>2, 3</sup>  $D = kt^n$ , where  $D$  is the average grain diameter;  $k$ , a constant dependent only upon temperature;  $t$ , the

time; and  $n$ , a constant; the data obtained here conformed closely enough to this formulation to be presented in this way. On this basis, grain-growth data for zirconium, whose initial grain size is 0.009 mm at the temperature levels 640°, 680°, 720°, 760°, and 800°C, are plotted in Fig. 2. The data for 640°, 680°, and 720°C are seen to constitute a family of parallel straight lines over the entire 100 hr of the study. At 760° and 800°C, however, the growth rate shows an abrupt increase after an initial stage, and a new family of curves appears. The grain-growth data for series B and C are given in Fig. 3. Considering first the B series, it is seen that at 640°C, a long incubation period was observed, during which no noticeable change in the average grain diameter was detected. After more than 35 hr, however, grain growth began and proceeded normally. At 720° and 800°C grain growth occurred at the shortest time examined, and it is seen that the data at 640°, 720°, and 800°C form a family of straight lines (Fig. 3). A similar incubation period, followed by normal grain growth was noted for the C specimens which started at the same initial grain size. Also grain growth in this material proceeded consistently, a family of straight lines again expressing the observed behavior.

In Fig. 2, in addition to a plot of the A series, typical curves for series B at 680°C, and C at 760°C are given (there is no need for including all the B and C curves because within each series the curves are parallel). Since the initial grain size for the B and C series was much larger than that of A, the grain-growth curves for the former two series for corresponding temperatures were always shifted to a higher grain-size level. It should be noted, however, that the rate of change of  $\log D$  with  $\log t$  for series B at all temperatures is the same as in series A at 760° and 800°C, while the series C curves have a slope or rate of change of  $\log D$  with  $\log t$  intermediate between those of series A and C.

These grain-growth results very definitely reflect the effect of the second phase. Cold swaging the deposited rod caused fragmentation of the second phase, which appeared in the deposited rod as parallel platelets (with different orientations in different grains). For the A series, the subsequent recrystallization anneal caused the fine inclusion particles to spheroidize, and the structure shown in Fig. 4a resulted. Further, when the grain-growth anneals were carried out, these dispersed particles inhibited, but did not prevent, grain-boundary migration. Simultaneously, however, the small particles of second phase preferentially dissolved, and diffusion of the second-phase constituents occurred to permit the larger particles of the second phase to grow at the expense of the smaller ones. The inhibiting effect of the particles, especially as long as they remained intragranular, continued but became less effective as the size increased. Temperature, of course, had the effect of accelerating this spheroidizing process as evidenced by the fact that at 720°, 10 hr were required for agglomeration of this second phase into large angular inclusions in the grain boundaries, but within 3 hr at 800°C agglomeration was obtained (Fig. 4b).

The grain-growth curves for metal A at 640°, 680°, and 720°C and the initial part of the 760° and 800°C curves thus represent the rate of boundary migration under the inhibiting influence of the uniformly distributed second-phase particles which were simultaneously undergoing spheroidization and agglomeration. When this spheroidization proceeded to the

Fig. 2—Isothermal grain-growth curves for A series of zirconium at 640°, 680°, 720°, 760°, and 800°C. Curve for growth of series B, at 680°, and series C at 760°C are superimposed.

point where the intragranular particles had disappeared and large angular second-phase particles appeared in the grain boundary (but not preferentially in the dihedral angles), grain growth became much more rapid. A new family of grain-growth curves was thus obtained.

No indication of a critical temperature below which an equilibrium grain size existed, as found by Beck,<sup>2</sup> is seen in these data. Continuous grain growth in the presence of dispersed second-phase inclusions probably occurred in zirconium of this study because at all the annealing temperatures the second phase was at least partially soluble. This is qualitatively in agreement with Beck's<sup>2,3</sup> work on aluminum-manganese alloys which showed that when the second phase is soluble normal continuous grain growth occurs.

In the B series however, the second phase was initially agglomerated into large particles at grain boundaries during the recrystallization and preparation anneal as shown in Fig. 5a. At the lower temperatures, then, these particles did not have as pronounced an inhibiting effect as did the finer dispersed particles in the A material; thus a family of curves (Fig. 3) holds over the entire temperature range from 640° to 800°C, instead of only at 760° and 800°C as in series A. In the C series, the second-phase distribution was similar to that in the A series before the grain-growth anneals, except that the particles were initially larger. During the grain-growth anneals, however, these particles did not agglomerate as completely as they did in the A series. An inhibiting effect of intragranular second phase thus persisted during the entire time and at all temperatures. Consequently, the grain-growth curves for the C series are almost parallel to those of the A

Fig. 3—Isothermal grain-growth curves for the B and C series of zirconium from 640° to 800°C.

series at 680°C, then gradually increased in slope at 720° and 800°C, but never attained the grain growth of the A and B series at 720°, 760°, and 800°C. Thus, since the same degree of agglomeration of the second phase in the grain boundaries was not accomplished in the C series as was always present in the B series

Fig. 4—Microstructures of zirconium from grain-growth studies on series A, 10 pct HF in glycerine etch. a (top)—3 hr at 720°C. X300. b (center)—3 hr at 800°C. X300. c (bottom)—50 hr at 800°C. X200.

throughout and in the latter stages of the A series, the inhibiting effect of the second phase gave grain-growth characteristics which were intermediate between the A and the B series.

Dispersed second-phase particles have an inhibiting effect on grain growth either directly or indirectly by obstructing the movement of atoms across grain boundaries. It is noted that, for a given constant amount of second phase, the finer the particles, the greater was the inhibiting effect. This is reasonable if it is accepted that a metal inclusion interface impedes the migration of a grain boundary, because the smaller the particle, the greater is the surface area for a constant amount of second-phase impurities. When the second phase is agglomerated in the grain boundaries, grain growth may be retarded for two reasons: 1—the actual grain boundary or interfacial area across which atoms may migrate may be decreased, or 2—changes in grain-boundary curvature accompanying growth may be prevented by the segregation of second phase in the dihedral angles. That this latter inhibiting effect was present in this work is shown by the fact that the surface of numerous A series specimens, which contained no second phase after being annealed 50 hr at 800°C, grew extremely large and very rapidly, while the internal grains in the presence of the second phase preferentially at the dihedral angles remained comparatively small. It is further noted that the surface grain boundaries are perpendicular to the surface and the dihedral angles are approximately the equilibrium value of 120°C, as predicted by Harker and Parker<sup>4</sup> and others.<sup>5</sup> Also, no additional growth of these surface grains was noted after 100 hr at 800°C, Fig. 4.

The constant slope of the series A growth curves for 640°, 680°, and 720°C establishes that  $n$ , in the expression  $D = kt^n$ , is a constant. This in turn designates that one mechanism of growth is operating at these three temperatures, and thus calculation of the energy of activation of that process can be made. This can be done by means of the relation first proposed by Arrhenius<sup>6</sup> and applied to grain growth by Burke<sup>3</sup> and others; that is, the rate of grain growth  $= Ae^{-Q_g/RT}$ , where  $A$  is a constant (independent of temperature);  $Q_g$ , the energy of activation for grain growth;  $R$ , the universal gas constant; and  $T$ , the temperature in degrees absolute. Using this equation, the energy of activation,  $Q_g$ , has been evaluated graphically for series A at 640°, 680°, and 720°C as shown in Fig. 6. The slope of this line divided by  $R$ , the universal gas constant, yields the value 68,800 cal per mol. Calculation of  $Q_g$  for the higher temperature data and for the B series from

Fig. 6—Plot of time necessary to attain a grain size of 0.02 mm from an initial grain size of 0.009 mm vs. reciprocal of the corresponding absolute temperature.

680° to 720°C, inclusively, yields the value 55,000 cal per mol. These values represent the energies of activation for zirconium containing the second phase, 1—uniformly distributed, and 2—preferentially in the grain boundaries, respectively.

The incubation period in the 640°C curves of the B and C series is now being investigated more completely for zirconium over a wide range of temperatures, and these data will be reported in a later paper. Although commonly observed, present grain-growth theories neither predict nor explain the existence of an incubation or induction period for grain growth subsequent to complete recrystallization, but when a more precise mechanism is established and associated with the energetics of the process, the phenomena should be explicable.

**Recrystallization:** The isothermal softening curves obtained for zirconium for the temperatures 450°, 500°, and 550°C at 20 and 50 pct reduction levels are found in Figs. 7 and 8. It is seen that for any one distribution of second phase and amount of deformation the rate of softening is principally dependent upon temperature, increasing as the latter increases. The incubation period, however, for the metal deformed 50 pct is appreciably shorter than for zirconium deformed 20 pct. The overall rate of recrystallization increases with the amount of prior deformation. Work hardening as a result of cold work raises the initial hardness level, but the hardness difference in the fully annealed specimens may be either a result of previous annealing treatments or an effect of prior deformation on recrystallized grain size. It is unlikely that the higher final hardness is the residual effect of greater prior deformation, per se.

Definite effects of second-phase distribution and possibly solid solution can also be seen in these data. The  $\alpha_a$  form is slightly harder and appears to possess a greater capacity for work hardening than the  $\alpha_b$  form, since the hardness differential increases with deformation. This differential is maintained during annealing with the result that the shapes of the softening curves for both temperatures at the same reductions are similar. A considerably longer incubation period is required before softening begins in the

$\alpha_a$  structure than in the  $\alpha_b$ . In the  $\alpha_a$  structure, Fig. 1a, it is seen that the same phase appears as parallel platelets, and this lamellar structure has the effect of retarding softening.

Although the metallographic difficulties encountered with zirconium in the cold-worked state made it impossible to extensively use the classical metallographic approach to the study of recrystallization, some metallographic data have been obtained for correlation of hardness with percentage of recrystallization. These data yielded the correlation between hardness and the fraction recrystallized given by the relationship:

$$x^2 = 1.038 \cdot (h_o - h_x) / (h_o - h_i)$$

where,  $x$  is the percentage recrystallized;  $h_x$ , the hardness at  $x$  pct recrystallized;  $h_o$ , the cold-worked hardness; and  $h_i$ , the full-annealed hardness. This relationship holds for all but the initial phase of the softening process. This result is to be compared to that of Cook and Richards<sup>2</sup> and others<sup>6</sup> who found that pure copper obeyed the relationship of  $x = (h_o - h_x) / (h_o - h_i)$ . This latter relationship indicates that softening occurs in direct proportion to the extent of recrystallization. The relationship developed from the present data, however, indicates that softening occurs in this commercially pure grade of zirconium in direct proportion to the square of the percentage recrystallized.

This relation is believed to reflect that a diffusion process associated with and effecting a redistribution of the second phase is occurring simultaneously with recrystallization. This diffusion process continuously changed the solid-solution composition, especially in the early phases of the recrystallization anneal, and a corresponding change in hardness occurred. The hardness change resulting after the various anneal-

Fig. 7—Softening curves for  $\alpha_a$  and  $\alpha_b$  zirconium at 450°, 500°, and 550°C for 20 pct reduction.

Fig. 8—Softening curves for  $\alpha_a$  and  $\alpha_b$  zirconium at 450°, 500°, and 550°C for 50 pct reduction.

ing times is thus a composite of softening resulting from recrystallization and hardening resulting from changing the composition of the continuous zirconium solid-solution phase.

Thus, since the parameter (hardness) used to follow recrystallization has also been affected by diffusion of either the second-phase components or residual oxygen in the sample tubes, the absolute rates of recrystallization of zirconium cannot be obtained from the present data. The relative rates of recrystallization revealed by these hardness measurements, however, can be used as a reliable guide to establish fabrication practice of comparable grades of pure zirconium.

No attempt is made to evaluate an energy of activation for recrystallization, since the absolute rates of recrystallization at the various temperatures cannot be ascertained. It is pertinent to point out, however, that the general shape of all the curves is similar, indicating that the same recrystallization mechanism is operative throughout and that this mechanism is independent of prior deformation and prior heat treatment.

### Conclusions

1—The isothermal grain-growth data for zirconium follows the relation:

$$D = kt^n$$

2—Second-phase inclusions have pronounced effects on grain growth.

a—In the presence of dispersed second-phase inclusions, grain growth of zirconium was retarded but growth was continuous at temperatures from 640° to 800°C.

b—The retarding effect of the second phase when agglomerated in the grain boundaries was less than when it was dispersed throughout the grains.

c—The entire elimination of the second phase resulted in accelerated grain growth.

3—The energy of activation for grain growth of zirconium in the presence of a dispersed second phase is 68,800 cal per g atom as compared with a value of 55,000 cal per g atom when the second phase is agglomerated in the grain boundaries.

4—Increasing the temperature increases the rate of recrystallization of zirconium independently of prior heat treatment and deformation.

5—The rate of recrystallization increases and the incubation period decreases with increased amount of cold work.

6—Solid solutions of oxygen or the second-phase constituent early in the recrystallization anneal increased the hardness so that appreciable recrystallization occurred before it was revealed by softening. The two structures of zirconium heat treated above and below the transformation temperature contained appreciably different distributions of the second phase, and had different recrystallization characteristics. Heat treating above the transformation temperature results in more work hardening and slightly higher hardness readings than below, and this difference persists throughout the entire anneal-

ing period. When the second phase occurs as platelets, recrystallization is retarded.

### DISCUSSION, D. Turnbull presiding

**H. H. Hausner and H. S. Kalish** (*Sylvania Electric Products, Inc., Bayside, L. I., N. Y.*)—We wish to congratulate the authors for their interesting paper and would like to call their attention to our paper.<sup>9</sup> The difference between the authors and our investigations lies mainly in the fact that the authors studied the recrystallization and grain growth of solid, cold-worked material, whereas we investigated the grain growth during sintering and the effect of sintering conditions on the grain size. We found an excellent correlation between grain size and the density of the respective specimen with no respect to whether this density was achieved by short-time sintering at high temperature, or by long-time sintering at lower temperatures. We found further that the grain size obtained under certain sintering conditions depends on the raw material used for the compact. The rate of grain growth was considerably greater with zirconium hydride powder than with zirconium powder used as a raw material.

**F. J. Dunkerley** (authors' reply)—The work of Dr. Hausner and Mr. Kalish on grain growth during the sintering of powdered zirconium came to our attention after this work was completed, but it is gratifying to find their results are in good agreement with our data on the wrought metal. We too noted the pronounced inhibiting effect of second-phase impurities on grain growth. In Fig. 4c micrographic evidence of accelerated growth in the absence of the second phase is shown. This phenomena is probably responsible for the more rapid grain growth noted for the zirconium hydride powder.

# Chromium-Nickel Phase Diagram

by David S. Bloom and Nicholas J. Grant

An investigation of the Cr-Ni system has revealed that there exists a eutectoid transformation at about 1180°C. The transformation in chromium implied by the eutectoid reaction was detected at about 100°C below its melting point. Associated with the eutectoid transformation, a metastable transition structure has been found.

THE Cr-Ni phase diagram is shown in current literature to be a simple eutectic system in which the high chromium end of the diagram is incompletely determined, Fig. 1. The last investigation of this system was undertaken in 1936.<sup>1</sup> Because of limitations in metal purity, especially of chromium, and temperature measuring techniques, the diagram should be accepted with some reservations, as was indicated by Hansen.<sup>2</sup> For example, the presence of the compound Cr<sub>2</sub>Ni, with a tetragonal structure,<sup>3</sup> remains unverified and incompatible with the simple eutectic diagram.

The work reported here began because of discrepancies that appeared in experimental studies in the binary alloys Cr-Ni and in the ternary system Cr-Mo-Ni. The existing binary Cr-Ni diagram failed to provide a complete explanation of observations made by microscope, X-ray, and thermal analyses.

## Experimental Methods

The materials employed were of a higher degree of purity than were available to previous investigators. The Mond nickel used had a nominal purity of 99.87 pct, while the electrolytic chromium analyzed 99.03 pct with the major impurity being 0.5 to 0.7 pct oxygen with some iron. All alloys were melted in a vacuum furnace to remove dissolved gases, sufficient carbon was added to the charge to combine with all the oxygen as CO. Final analysis determined the carbon as about 0.02 pct and the oxygen around 0.06 pct or slightly more. Stabilized zirconia crucibles and thermocouple protection tips were used throughout and contributed no detectable impurity to the melts, as long as the oxygen in the chromium was kept low. Heats averaged about 250 g, which permitted about 2 in. of the thermocouple protection tips to be submerged. The temperature drop across the thermocouple protection tip was determined to be about 3°C, a minor source of error.

The alloys, after removal from the vacuum furnace, were placed in a furnace operating in a purified argon atmosphere for the thermal analyses. An-

Discussion on this paper, TP 3155E, may be sent, 2 copies, to AIME by Jan. 1, 1952. Manuscript, April 18, 1951; revision, Aug. 22, 1951. Detroit Meeting, October 1951.

Fig. 1—Cr-Ni phase diagram drawn from the diagram in the Metals Handbook, 1948 Edition.

nealed wolfram-molybdenum thermocouples provided the primary means of temperature determination, though a Pt-Pt-10 pct Rh couple was employed for a check when possible. A sensitive, high-speed Leeds and Northrup Speedomax recording potentiometer indicated the thermocouple output.

X-ray diffraction patterns were obtained primarily on a Norelco unit, which permitted diffraction angles only up to 45° ( $2\theta = 90^\circ$ ). In general, either rotated or stationary solid samples were used, because it later evolved that many samples were susceptible to transformation resulting from the cold working involved in pulverizing. It was also noted that rotating a sample sometimes suppressed weak lines, so, usually, samples were not rotated. Later a high temperature camera was adapted for use at temperatures up to 1400°C on the Norelco unit utilizing both solid and powdered samples. Unless otherwise noted, all X-ray patterns were made with a chromium tube and a vanadium filter. Further-

Fig. 2—Cr-Ni diagram.

more, because many samples were sensitive to mechanical polishing, practically all samples were polished and etched electrolytically. The etch generally used was a mixture of concentrated nitric acid, sulphuric acid, and phosphoric acid.

All heat treating was done in a resistance furnace in a purified-helium atmosphere. Inasmuch as the cooling rate turned out to be critical in some alloys, efforts were expended to obtain the fastest quench possible.

### Experimental Results

To facilitate the discussion of the experimental results it seems advisable to introduce here the phase diagram, Fig. 2, which resulted from this investigation. The  $\alpha$  field is the body-centered cubic chromium solid solution; the  $\gamma$  field is the face-centered cubic nickel phase, while the  $\beta$  phase is a proposed high temperature chromium structure, thought to be face-centered cubic.

In Figs. 3 through 8 are shown the as-cast microstructures of some representative alloys. Fig. 3 shows a 90 Cr-10 Ni alloy in which it can be noted that the grain boundaries do not follow the dendritic structure. This indicates that recrystallization has occurred after solidification. Fig. 4 represents an alloy of 65 Cr-35 Ni, the structure of which cannot

be explained by the existing phase diagram. A 55 Cr-45 Ni alloy is presented in Fig. 5. It can be seen that there is a two-phase structure within the chromium-rich dendrites (the darker regions). This structure does not conform to that expected from the simple eutectic phase diagram, either. Fig. 6 reveals the structure of the eutectic composition (51 Cr-49 Ni); at a higher magnification the chromium-rich phase sometimes reveals an unanticipated internal structure. Figs. 7 and 8 show a 45 Cr-55 Ni alloy, and it will be noticed that there are three phases present. Further, at the higher magnification of Fig. 8, a eutectoid structure can be identified. From these structures alone the correctness of the simple eutectic diagram is subject to doubt.

The next series of microstructures are from specimens quenched from 1150°C, after first being solution-treated at 1325°C and furnace-cooled to 1150°C. Fig. 9 is of a 60 Cr-39 Ni-1 Mo alloy and comparing the structure with that of a 55 Cr-45 Ni alloy (Fig. 10) reveals the relation of the eutectoid structure to the eutectic structure.

A 45 Cr-55 Ni alloy is reproduced in Fig. 11 and shows the interesting form that the precipitate of the chromium-rich phase takes. Fig. 12a is the X-ray diffraction pattern corresponding to the specimen reproduced in Fig. 9, i.e., the 60 Cr-39 Ni-1 Mo alloy. The molybdenum in this alloy was inadvertently picked up from the radiation shield during melting. There was no visible difference between this alloy containing about 1 pct Mo and a similar alloy with no molybdenum, but the presence of the molybdenum permitted the retention of the high temperature phase (yet to be discussed), with no decomposition whatsoever, a condition unobtainable in a binary alloy. The apparent effect of the molybdenum was to stabilize the high temperature phase, fortunately.

There is an important difference between alloys quenched from 1250°C and those quenched from 1150°C as may be seen by comparing Figs. 13 through 15 with those just discussed. Fig. 13 is of the same alloy as shown in Fig. 9 and its X-ray diffraction pattern is shown in Fig. 12b. Comparison of Fig. 12b with Fig. 12a indicates that there is a fundamental difference between the two structures; this is also obvious from the micrographs. Fig. 14 shows the same alloy as in Fig. 10; Fig. 15 is the eutectic composition.

To corroborate the existence of the  $\alpha$  to  $\beta$  transformation as shown in the phase diagram, resort was made to a high temperature X-ray camera. The transformation temperature was later determined from dilatometer work to be at 1180°C. In order to

obtain all the existing lines, as it was found that solid samples did not always produce all lines, powdered samples were used. These samples were compacted and then placed in the camera, but unfortunately at the temperatures of interest these samples soon sintered into solid specimens. Further, at these temperatures the extremely large thermal gradients in the sample precluded any accurate determination of the transformation temperature.

Figs. 16a and b show that a transformation did occur at a temperature of about 1200°C. Fig. 16a shows the room temperature diffraction pattern. Fig. 16b shows the same  $2\theta$  range after the transformation has occurred. It is not possible to ascertain the crystal structure of the high temperature phase from this pattern, but it is apparent that a transformation has taken place. The absence of the  $\beta$ -Cr (111) line at about 41° ( $2\theta$ ) can be explained by the sintering of the powder compact into a solid mass.

Inasmuch as the eutectoid transformation implies a crystal transformation in pure chromium, an effort to detect this transformation was made. The transformation in chromium must take place at a temperature above 1700°C, because the specific

Fig. 16—X-ray diffraction patterns.  
a (upper)—Pattern taken at room temperature of 63 Cr-37 Ni alloy showing the  $\alpha$  chromium and  $\gamma$  nickel lines. Copper tube, nickel filter.  
b (lower)—Pattern taken at about 1200°C of 63 Cr-32 Ni alloy in high temperature camera. Accuracy of lines cannot be better than  $\pm 0.2^\circ$  because of shrinkage due to sintering and expansion of furnace. Comparing Fig. 16a with this figure it can be seen that the  $\gamma$  nickel lines have shifted to the left. Copper tube, nickel filter.

resistance has been measured up to this temperature and no anomalies discovered.<sup>4</sup> However, chromium with a small amount of oxygen (1.0 pct) showed a definite discontinuity at about 1600°C, and this discontinuity was ascribed to a eutectic in the Cr-O system. Fig. 17a shows a cooling curve of pure chromium. It will be noticed that there is an unusual change of slope about 100° below the solidification temperature (more accurate values were obtained at lower cooling rates). In Fig. 17b is shown a solidification curve of pure nickel in the same apparatus under similar conditions in order to emphasize the change of slope which exists in the chromium cooling curve. Efforts to retain the high temperature phase by quenching liquid chromium were not successful; however, in Fig. 18 is shown a 90 Cr-10 Ni alloy which was quenched from the liquid. It is evident that here there are two phases present. In Fig. 3 the same alloy is shown as-slowly-cooled, and, as was mentioned before, the fact that the grain boundaries do not follow the dendritic

Fig. 19—65 Cr-35 Ni alloy as-quenched from 1250°C, after electropolishing only. This sample was rotating while pattern was being obtained.

structure is indicative of recrystallization after solidification.

In order to identify the high temperature  $\beta$  chromium it was necessary to use quenched specimens. It had been hoped that by employing a copper-anode X-ray tube and the high temperature camera it would be possible to find additional lines, but it seems that all higher angle lines were so diffuse at 1250°C that they were not recognizable. This same diffuseness of high angle lines was obtained when using quenched specimens in a new Norelco unit which measures  $2\theta$  values up to 150°. Consequently, only the lines present in Fig. 12b were available for study. In this connection it is of interest to note that this same diffuseness of lines in this system was reported by Jette and others in 1934.<sup>5</sup>

The available lines fit a face-centered cubic crystal with a lattice constant of 3.76 kx units; considering the metastable structure which exists, and yet to be discussed, the face-centered cubic crystal seems the most likely structure.

If the lattice constant of a face-centered cubic chromium is calculated, taking into consideration the correction in interatomic distance involved in the change in coordination number corresponding to a change from a body-centered cubic to a face-centered cubic, the result is a lattice dimension of 3.68 kx. Remembering that the face-centered cubic struc-

b (lower)—As-quenched from 1250°C after repeated electrolytic polishing of an initially metallographically polished specimen.

ture depicted in Fig. 12b is saturated with nickel, the disparity in lattice dimensions is not too bad.

Delineation of the fields above the eutectoid temperature, while desirable, is extremely difficult because of the rapidity of quenching which is needed in order to retain the high temperature phase, particularly when in contact with the low temperature  $\alpha$ -Cr phase.

### Metastable Phase

In Fig. 19 is reproduced the diffraction pattern of a 66 Cr-34 Ni alloy as-quenched from 1250°C. In this pattern can be identified the lines due to low temperature  $\alpha$  Cr,  $\gamma$  Ni, high temperature  $\beta$  Cr, and a transition phase  $\alpha'$ . From this pattern the  $\alpha'$  phase can be tentatively identified as a body-centered tetragonal structure with an axial ratio of 1.09. However, from comparison with other patterns it has been determined that the axial ratio is not invariable. The presence of this body-centered tetragonal structure accounts for the previous report<sup>3</sup> of such a structure in this system, but the explanation offered of such a structure, that it is a compound  $\text{Cr}_2\text{Ni}$ , now appears to be incorrect.

It is interesting to note that in the similar system, Fe-C, the tetragonality of the transition structure

Fig. 22—65 Cr-35 Ni alloy after quenching from 1250°C, powdering, and being separated magnetically. This is magnetic portion.

(martensite) is considered to be due to the interstitially located carbon atoms; this effect cannot be presumed to be operative here.

The determination of phases is further complicated by the effect of polishing on the  $\beta$  phase and the metastable structure. Figs. 20a, b, and c are all of the 66 Cr-34 Ni composition quenched from 1250°C. This sample was first mechanically polished and lightly electrolytically etched as shown in Fig. 20a. The effect of a deeper electrolytic polish and etch of the same sample is shown in Fig. 20b. A yet deeper polish and etch resulted in Fig. 20c. It is obvious that mechanical polishing has transformed the alloy. The X-ray pattern of the alloy after repeated polishing is shown in Fig. 21b; the extra lines are due to the metastable phase which is probably a result of the mechanical work. Referring back to Fig. 20c, there is no explanation of the ripple appearing in the matrix of the specimen. Further evidence of the effect of mechanical working on the  $\beta$  phase is given in Fig. 12c, which shows the X-ray diffraction pattern of the same alloy and specimen as shown previously in Fig. 12b, except that the specimen has been polished lightly on 600-grit paper. A change in the location of the lines is evident.

Another facet of interest of the transition structure is its magnetism. If a eutectoid alloy is quenched from above the eutectoid temperature, and then powdered, portions of the powder will be rather strongly ferromagnetic. In Fig. 22 is presented the diffraction pattern of the magnetic portion of such a powder. The sample was separated by collecting the particles adhering to a small permanent magnet which had been inserted into the powder. While the pattern shows the chromium phase to predominate, there are indications of a partially formed nickel phase. The  $\gamma$  (200) line is actually comprised of two lines as confirmed by other patterns.

### Conclusions

The investigation of the Cr-Ni system has resulted in the following conclusions:

- 1—There is a transformation in chromium at about 1830°C tentatively identified as a change from a body-centered cubic to a face-centered cubic structure.
- 2—The addition of nickel lowers the transformation temperature, until at about 65 Cr-35 Ni a eutectoid temperature of about 1180°C results.
- 3—In alloys having approximately the eutectoid composition and quenched from above the eutectoid temperature, it is possible to produce a body-centered tetragonal metastable structure.

# Free Energy of Formation of Cementite And The Solubility of Cementite in Austenite

by L. S. Darken and R. W. Gurry

The solubility of cementite in austenite is computed by thermodynamic methods from the observed solubility of graphite. It is found that the solubility of cementite is greater than that of graphite in the entire austenite temperature range. Thus the prior discrepancy between this portion of the phase diagram and the observed metastability of cementite is partially resolved.

FOR several years it has been apparent that a serious discrepancy exists in certain observations pertaining to the Fe-C system. Direct experimental data indicate: 1—That the curve representing the solubility of graphite in austenite<sup>1-3</sup> crosses that for cementite<sup>4</sup> at about 945°C as shown in Fig. 1. 2—That graphite and austenite saturated therewith are stable<sup>1</sup> relative to cementite at all temperatures between the eutectoid, about 723°C, and the eutectic, about 1153°C.

These observations are mutually incompatible in view of a well-known consequence of the second law of thermodynamics, namely, that the stable phase (presumably graphite at all temperatures) has a lower solubility than the metastable phase (presumably cementite). Hence either 1 or 2 above must be in error; either the measured solubility of graphite or of cementite, or the observation as to the stability of graphite, is in error.

Our present purposes are: 1—To collate the available data on cementite and prepare a table of  $H^\circ - H_0^\circ$  and of  $(F^\circ - H_0^\circ)/T$ . This tabular method

seems the best and most convenient way to represent the heat and free energy of formation. 2—To determine whether the measured solubilities of cementite and graphite in austenite are in accord with the above table and the measured thermodynamic properties of austenite, in order to resolve, if possible, the existing paradox of these two solubilities.

## Enthalpy of Cementite

The enthalpy of cementite at 273°K,  $H_{273}^{\text{cem}} - H_0^{\text{cem}}$ , was computed by integration of the low temperature heat capacity as measured by Seltz, McDonald, and Wells<sup>5</sup> (68° to 298°K) and as given by the Debye functions recommended by them (0° to 68°K); the result is included in Table I. At higher temperature  $H^{\text{cem}} - H_{298}^{\text{cem}}$  is given by Kelley<sup>6</sup> who used the data of Naeser<sup>7</sup> (298° to 1037°K) and of Umino<sup>8,9</sup> (273° to 1923°K).

We have recalculated  $H^{\text{cem}} - H_{273}^{\text{cem}}$  from the data of Umino<sup>9</sup> in the following way. In the equilibrated alloy at temperature the weight fraction of cementite

is  $\frac{\text{Pct C} - \text{Pct C}^\gamma}{\text{Pct C}^{\text{cem}} - \text{Pct C}^\gamma}$ , designated  $f(C)$ , and the

Fig. 1—Solubility of cementite and of graphite in austenite.

L. S. DARKEN, Member AIME, and R. W. GURRY, are associated with the Research Laboratory, U. S. Steel Co., Kearny, N. J.

Discussion on this paper, TP 3128E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, May 18, 1951. New York Meeting, February 1952.

Fig. 2—Determination of the enthalpy of cementite from Umino's data on Fe-C alloys of 1.33 to 5.07 pct C equilibrated at 900°C.

weight fraction of austenite is one minus this quantity. The heat evolved on quenching 1 g of the alloy to 0°C, designated  $Q$ , is therefore:

$$Q = Q^{cem} f(C) + Q^{\gamma} [1 - f(C)]$$

where  $Q^{\gamma}$  is the heat liberated by 1 g of austenite on cooling (perhaps somewhat vague on account of the uncertainties of transformation) and  $Q^{cem}$  is  $H^{cem} - H_{273}^{cem}$ . If  $Q$  be plotted against  $f(C)$  the intercept at  $f(C) = 1$  is  $H^{cem} - H_{273}^{cem}$  and the uncertainty as to  $Q^{\gamma}$  is eliminated by the extrapolation. A typical plot is shown in Fig. 2. It will be noted that the extrapolated value is substantially independent of whether or not the correction (for austenite decomposition) suggested by Umino is used.

The results differ somewhat from those reported by Umino. It is believed that the recalculated values represent more truly Umino's experimental determinations, and these have been plotted along with Naeser's and Umino's original determinations in Fig. 3. The final curve differs only slightly from Kelley's, except in the extrapolated portion which is of no interest for the purpose of this paper, but is included in order that the results may be used at higher temperature if desired. Combination of this with  $H_{273}^{cem} - H_0^{cem}$  from the data of Seltz, McDonald, and Wells permits the evaluation of  $H^{cem} - H_0^{cem}$  over the entire range as given in Table I.

### Free Energy of Cementite

Browning, DeWitt, and Emmett<sup>10</sup> have published recently the results of their careful investigation of the equilibrium between cementite,  $\alpha$  iron, and mix-

Fig. 3—Enthalpy function for cementite.

tures of methane and hydrogen in the temperature range 348° to 468°C. The results are in good agreement with the earlier investigation of Watase<sup>11</sup> (450° to 603°C) on the same equilibrium. The greatest deviation in Browning, DeWitt, and Emmett's experimentally determined equilibrium constant from a smooth curve is about 10 pct, corresponding to a precision of about 150 cal in the free energy of formation. The short temperature range gives rise to a corresponding uncertainty of perhaps 400 cal in their determination of the heat of formation of cementite.

Combination of these recent results of Browning, DeWitt, and Emmett with other information affords an opportunity for an improved evaluation of the free energy of cementite and a precise determination of the relative stability of graphite and cementite. The solubility of graphite and cementite in austenite is generally believed to be known with considerable precision in the vicinity of the eutectoid; however, preliminary calculations indicated that these data are somewhat inconsistent with the other data to be considered and hence no great weight was placed upon them here. The temperature difference (about 7°C) between the graphite eutectic and the cementite eutectic of the Fe-C system permits (in conjunction with thermodynamic data on austenite) an evaluation of the free energy of formation of cementite in the vicinity of 1153°C. The heat of

formation and the entropy of formation as evaluated from the low temperature heat capacity are also pertinent. These various data are collated in the following way.

The function  $\frac{F^{cem} - H_0^{cem}}{T}$  may be obtained as  $\int_0^T (H^{cem} - H_0^{cem}) d(1/T)$  or more conveniently as  $-\int_0^T \frac{H^{cem} - H_0^{cem}}{T^2} dT$ . The plot for the graphical

integration is shown in part in Fig. 4. Considerable uncertainty is involved in the low temperature portion of the integration; experimental error is greatly magnified here due to the form of the curve which, as usual, contributes a rather large area in this region. In order to eliminate this source of error at higher temperature, this error, which is a constant for temperatures above 25°C, has been represented by  $\delta$  and an asterisk has been used to denote that the integral is in error by the value of  $\delta$ . Thus,

$$\frac{F^{cem} - H_0^{cem}}{T} = \delta - \left[ \int_0^T \frac{H^{cem} - H_0^{cem}}{T^2} dT \right]^* \quad [1]$$

The free energy of formation of cementite,  $\Delta F$ , may be obtained by combining the above function with similar functions for iron<sup>12</sup> and for graphite:<sup>13</sup>

$$\frac{F^{\text{cem}} - H_0^{\text{cem}}}{T} - 3 \frac{F^{\text{Fe}} - H_0^{\text{a-Fe}}}{T} - \frac{F^{\text{gr}} - H_0^{\text{gr}}}{T} = \frac{\Delta F - \Delta H_0^\circ}{T} \quad [2]$$

Combining eqs 1 and 2:

$$\left[ \int_0^T \frac{H^{\text{cem}} - H_0^{\text{cem}}}{T^2} dT \right]^* - 3 \frac{F^{\text{Fe}} - H_0^{\text{a-Fe}}}{T} - \frac{F^{\text{gr}} - H_0^{\text{gr}}}{T} - \frac{\Delta F}{T} = - \frac{\Delta H_0^\circ}{T} - \delta \quad [3]$$

or, multiplying by  $T$  and changing signs:

$$T \left[ \int_0^T \frac{H^{\text{cem}} - H_0^{\text{cem}}}{T^2} dT \right]^* + 3 T \left( \frac{F^{\text{Fe}} - H_0^{\text{a-Fe}}}{T} \right) + T \left( \frac{F^{\text{gr}} - H_0^{\text{gr}}}{T} \right) + \Delta F = \Delta H_0^\circ + T\delta \quad [4]$$

Each of the first three terms on the left of eq 4 is now known as a function of temperature and a knowledge of  $\Delta F$  at two or more temperatures permits the evaluation of  $\Delta H_0^\circ$  and of  $\delta$ . By plotting

the left side of eq 4 against  $T$  a straight line should be obtained whose intercept and slope are  $\Delta H_0^\circ$  and  $\delta$ , respectively. The plot is shown in Fig. 5. The points represent: 1—the data of Browning, DeWitt, and Emmett near the extremes of their temperature range; 2—the data of Watase near the extremes of his temperature range; 3—values obtained from the graphite and cementite solubility lines of Fig. 1\* over approximately the range covered by the investigation of Mehl and Wells;<sup>4</sup> 4—a value computed from the observation that the iron-cementite eutectic is 7°C lower than the iron-graphite eutectic;\* and 5—crude values at room temperatures from the  $\Delta H_{298}$  of Naeser<sup>14</sup> and  $\Delta S_{298}$  from the measurements of Seltz, McDonald, and Wells, and Naeser.

In constructing the line of Fig. 5, it is seen that great reliance cannot be placed on the values from the vicinity of the eutectoid of the Fe-C system, as the corresponding points lie on a curve with slope appreciably different from that drawn; nevertheless the mean value fits well. The most weight has been

\* This computation involves the use of the activity of carbon and of iron in austenite. These are taken from the work of Smith.<sup>8</sup> The equations employed are:

$$\ln a_c = \ln \frac{N_c}{N_{\text{Fe}}} + 6.6 \frac{N_c}{N_{\text{Fe}}}$$

$$\ln a_{\text{Fe}} = - \frac{N_c}{N_{\text{Fe}}} - 3.3 \left( \frac{N_c}{N_{\text{Fe}}} \right)^2$$

Fig. 4—Plot for evaluating the free energy function for cementite.

given: 1—the new measurements of Browning, DeWitt, and Emmett; and 2—the value from the eutectic of the Fe-C system.

Choice 2 requires some justification since the selected line of Fig. 5 implies an error of about 0.08 pct C in the graphite or cementite eutectoid (or distributed between these two points) of the generally accepted temperature-composition diagram, Fig. 1. The previously available data on the temperatures of the two eutectics were discussed by Epstein.<sup>15</sup> Only two determinations are reported in which the two eutectic temperatures were measured on the same specimen. Table II gives the results. An investigation soon to be reported by Darken and Filser of this laboratory indicates a difference of about 6° (1153° and 1147°C). Hence it is considered justifiable to conclude that this temperature difference is undoubtedly 7°  $\pm$  2°. As will appear later, a difference of 5° near 1130°C is equivalent to this selected value in so far as Table I is concerned. As a 2° error here corresponds to only 100 cal, in the ordinate of Fig. 5, this figure of 7° difference in the eutectics seems one of the most firm foundations on which to base the calculations. For this reason the line of Fig. 5 is drawn through the corresponding point (on the extreme right).

From the large scale plot from which Fig. 5 was prepared  $\Delta H_0^\circ$  is found to be 5114 cal and  $\delta = 0.952$ . This value of  $\delta$  is added to each of the integrals

Fig. 5—Plot of a thermodynamic function pertaining to the formation of cementite, for the purpose of evaluating the error in the free energy function for cementite due to inaccuracy in the heat capacity measurements at low temperature.

Fig. 6—Plot showing the metastability of cementite.

according to eq 1 to give  $\frac{F^{\text{cem}} - H_0^{\text{cem}}}{T}$  which is

tabulated in Table I. Of course the error  $\delta$  also implies an error in  $H^{\text{cem}} - H_0^{\text{cem}}$ . This, however, is small and no correction is made to the enthalpy table.

A comparison of various thermodynamic functions for the formation of cementite as computed from the tabular values of the free energy function (and  $\Delta H_0^\circ = 5114$ ) with those from other sources is shown in Table III. The agreement of the present computation with experiment is seen to be satisfactory in substantially all respects—a conclusion previously inferred from Fig. 5.

### Solubility of Cementite in Austenite

From the free energy function for cementite, Table I, for  $\gamma$  iron<sup>12</sup> and for graphite<sup>13</sup> the activity product  $a_c a_{\text{Fe}}$ <sup>8</sup> for equilibrium with cementite was calculated over the range of temperature from the Fe-C eutectoid to the eutectic. Combination of this with the

\* 3 Fe (pure  $\gamma$ ) + C (graphite) = Fe<sub>3</sub>C (cementite).

† 3 Fe ( $\gamma$ , saturated with graphite) + C (graphite) = Fe<sub>3</sub>C (cementite).

‡ Standard state of carbon is taken as graphite.

graphite solubility of Fig. 1 and the carbon (and iron) activity data of Smith<sup>3</sup> leads, by successive approximations, to the activity,  $a_c$ , of carbon (relative to graphite) in austenite saturated with cementite, and thus to the cementite solubility. Values of these quantities are given in Table IV. The cementite solubility thus calculated, which represents our best estimate, is shown graphically in Fig. 1. Since the activity of carbon for the austenite-cementite equilibrium always exceeds unity (the minimum value is in the vicinity of 1340°K) it is apparent that cementite is metastable over this whole range. In Fig. 6 is plotted against temperature the free energy of formation of cementite from graphite and the Fe-C alloy in stable equilibrium with graphite. Cementite is seen to be metastable in the  $\alpha$  and liquid regions as well as the  $\gamma$ .

### Summary and Conclusion

The free energy function and the enthalpy function of cementite have been computed and tabulated from data which are believed to be reliable. The table is based on enthalpy (heat content) determinations, and equilibrium determinations. Other available data are shown to agree (within the experimental error) with the tables and the value 5114 cal for  $\Delta H_0^{\text{cem}}$  (the heat of formation of cementite at 0°K). It is concluded that cementite is metastable with respect to graphite and  $\alpha$  iron from 0°K to the eutectoid and also with respect to graphite and  $\gamma$  iron saturated with graphite from the eutectoid to the eutectic. The solubility of cementite in austenite computed from the experimentally determined solubility of graphite in  $\gamma$  iron is greater than the latter over the whole temperature range. The computed values differ from the generally accepted direct experimental determinations at both limits of the temperature range covered but are in agreement with them near the center of this range.

# Habit Phenomenon in the Martensitic Transformation

by E. S. Machlin and Morris Cohen

**G**RENINGER and Troiano<sup>1</sup> were the first to establish the fact that the habit planes of martensitic products are usually planes of high indices. In steels containing 0.55 to 1.4 pct C, the habit plane indices are  $\{225\}_A$ .<sup>\*</sup> In steels with more than 1.5 pct C and in Fe-Ni alloys, the indices are  $\{259\}_A$ . The presence of both habits in certain alloy steels has been reported recently.<sup>2</sup>

Several investigators<sup>3-6</sup> have subsequently attempted to provide an understanding of these complex habit relations. Bowles<sup>7</sup> work is the most recent and the most successful. Like Greninger and Troiano,<sup>8</sup> Bowles concluded that the transformation occurs in two steps, the first, a strain (or displacement) that is homogeneous throughout the volume of the martensitic plate, while the second is a strain that is homogeneous only within relatively small portions of the martensitic plate. The first strain yields the measured tilt of the specimen surface, but does not produce the final martensitic structure. This and the correct lattice orientations are achieved by the second strain. Bowles also reasoned that each strain could be described by the motion of a plane of no rotation and no distortion (hereinafter called the invariant plane) in a direction not necessarily contained in the plane.<sup>\*\*</sup> In applying these considerations to steels with  $\{225\}_A$  habits, Bowles found that the habit plane coincided with the invariant plane of the first strain, a result which signified that the atoms move along certain paths during the transformation. Whether this correlation results from the existence of some sort of a plate nucleus<sup>5</sup> lying along the invariant plane of the first strain, or whether the invariant plane primarily defines the

preferred directions of propagation of the first strain, will be discussed in a later section.

There are two obstacles to the general acceptance of Bowles' treatment: 1—it has not been shown that elements of his double-strain analysis are unique, and 2—it is not known whether his treatment applies to transformations yielding the  $\{259\}_A$  habit. Unless these two questions are resolved, the correlation between the habit and invariant planes in the  $\{225\}_A$  systems might be regarded as coincidental.

## Experimental Procedure

Using a 70 pct Fe-30 pct Ni alloy as an example of a  $\{259\}_A$  habit system, preliminary attempts were made to obtain a double-strain solution based on a Nishiyama<sup>\*\*\*</sup> set of orientation relations and on a Greninger-Troiano<sup>†</sup> set, adopting the stereographic technique described by Bowles<sup>5</sup> who used the Kurdjumow-Sachs<sup>††</sup> set in connection with the  $\{225\}_A$  habit. These attempts were unsuccessful because the method is essentially one of trial and error and requires either exceedingly good luck or a prior knowledge of the results being sought.

Consequently it was decided to measure independently the strain associated with the formation of a martensitic plate as well as the habit-plane indices of the particular plate. By means of matrix algebra, the measured strain was applied to the austenite lattice, whose orientation with respect to the strain was determined, in order to ascertain whether the resultant structure would have the lattice of martensite. This was not found to be the case, and hence it was assumed that the measured strain was the first of two Bowles-type strains, characterized by the motion of an invariant plane. A solution of this displacement was obtained in terms of the invariant-plane indices and the direction of motion of the atoms. Then the second strain

\* The matrices belong to two sets distinguished by the primes. Each matrix in a set can be obtained from another in the set by a 120° rotation about  $[111]_A$ . A matrix in one set has a mirror symmetry with one other matrix in the other set across a  $\{110\}_A$  plane. All matrices are crystallographically equivalent.

\*\* The  $\pm$  values in the table represent the scatter of successive readings on a given plate. Readings for all the plates fell within this uncertainty.

\*\*\* See Fig. 2 for the orientations of these plates relative to the parent austenite.

was calculated based on the Greninger-Troiano orientation relations. Finally the elements of both strains were checked using the Bowles stereographic manipulation.

Single crystals of a 70 pct Fe-30 pct Ni alloy<sup>7</sup> were grown from the melt in a molybdenum-wound vacuum furnace using a modified Bridgman technique. Specimens were prepared with three orthogonal faces parallel to  $(111)_A$ ,  $(\bar{1}\bar{1}0)_A$  and  $(\bar{1}\bar{1}2)_A$  respectively. Polishing scratches aligned parallel to the three orthogonal axes served as fiducial markings. The crystals were then partially transformed to martensite by cooling to about  $-40^\circ\text{C}$ . Many plates were formed in a burst.<sup>7</sup>

The specimen was then set into a jig which made it possible to observe microscopically the same martensitic plate on two orthogonal faces. Thus, the habit of the plate as well as the new directions of the fiducial lines within the plate could be measured. Fig. 1 illustrates the parameters that were recorded, and Table I presents a compilation of the results.

In the interpretation of these data the correspondence between subscripts and axes is as follows:

|   |                       |
|---|-----------------------|
| X | $[\bar{1}\bar{1}2]_A$ |
| Y | $[1\bar{1}0]_A$       |
| Z | $[111]_A$             |

For example,  $t_{zx}$  is the tangent of the angular dis-

placement of a scratch parallel to the Z or  $[111]_A$  direction in the X or  $[\bar{1}\bar{1}2]_A$  direction. The tangent is positive if the positive side of the  $[111]_A$  axis moves in the  $[\bar{1}\bar{1}2]_A$  direction. It is evident from Fig. 1 that the measurements for  $t_{xy}$  and  $t_{yz}$  are made on the Z or  $(111)_A$  face, for  $t_{yz}$  and  $t_{zy}$  on the X or  $(\bar{1}\bar{1}2)_A$  face, etc. The group of six tangents for a given plate comprise the nondiagonal components of a matrix:

$$T = \begin{pmatrix} t_{xx} & t_{xy} & t_{xz} \\ t_{yx} & t_{yy} & t_{yz} \\ t_{zx} & t_{zy} & t_{zz} \end{pmatrix} \quad [1]$$

This matrix will be called a  $T$  matrix inasmuch as it is composed mainly of tangents of angles. The diagonal components  $t_{xx}$ ,  $t_{yy}$ , and  $t_{zz}$  are not tangents; however they are not necessary for this analysis and no attempt was made to measure them. It will be shown later that the  $T$  matrix is related to the coordinate-transformation matrix. (Ref. 4 contains a good résumé of the elementary steps of matrix algebra as applied to the present problem.)

Of some 40 observed plates, it was found that to each permutation of the habit-plane indices there corresponded one and only one  $T$  matrix, and vice versa. The habit planes corresponding to each of the six matrices given in Table I are shown in Fig. 2 relative to the coordinates used in this study.

### Analysis of Results

It is first necessary to establish the relationships between the experimental quantities contained in the  $T$  matrix and the components of a coordinate-transformation matrix,  $A$ . The  $A$  matrix simply relates the initial and final positions of points in the transformed region. Thus, if the initial coordinates of a point are  $x, y, z$ , its final coordinates are given by:

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} a_{xx} & a_{xy} & a_{xz} \\ a_{yx} & a_{yy} & a_{yz} \\ a_{zx} & a_{zy} & a_{zz} \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad [2]$$

or

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = A \begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad [3]$$

The equations relating the  $T$  matrix to the required  $A$  matrix are derived in Appendix I.

If it is assumed that the transformation can be described by one homogeneous strain, then application of the measured strain to the austenite lattice should generate a body-centered cubic lattice (Fe-Ni martensite). This calculation is performed in Appendix II and the conclusion is reached there that the measured strain does not yield a body-centered cubic lattice. Hence, the single-strain concept of

Fig. 1—Showing scribed lines the directions of which change upon traversing a martensite plate. Meaning of  $t_{xy}$ , etc. illustrated with reference to three orthogonal axes.

Fig. 2—Habit planes on  $(111)_A$  projection, corresponding to the six variations in Table I.

Jaswon and Wheeler<sup>4</sup> does not apply to the transformation in this alloy.

The next step in the analysis was to determine whether the Bowles double-strain method is consistent with the data. The procedure was as follows:

1—Assume that an invariant plane of general orientation with respect to the axes used in this investigation (two parameters suffice to describe the position of the pole of the invariant plane with respect to the reference axes) moves in some direction lying in the  $(111)_A$  plane.†††

2—Set up a general coordinate-transformation matrix relative to the reference axes on the basis of such motion of the invariant plane. This matrix will then contain as unknowns the two parameters that specify the position of the invariant plane relative to the reference axes, a third parameter that specifies the direction of motion of the invariant plane,†††† and a fourth parameter that specifies the magnitude of the motion. Six equations are obtained by equating‡ the nondiagonal components of the  $A$  matrix (as calculated from the measured  $T$  matrix) to the corresponding components of the general coordinate-transformation matrix. Two of these equations have already been used because of the fact that the direction of motion of the invariant plane lies in the  $(111)_A$  plane. There are four equations left and hence it is possible to calculate the parameters defining the position of the invariant plane and direction of motion of the atoms.

These calculations have been performed in Ap-

††† The direction of motion must lie in the  $(111)_A$  plane because it is found experimentally (Appendix II) that the  $(111)_A$  plane does not rotate. Hence only a single additional parameter is necessary to specify the direction of motion.

†††† This is also the direction of motion of all the atoms.

‡ This step implicitly assumes the measured strain is a homogeneous strain.

§ The fact that one and only one invariant plane is found to be associated with a given  $T$  matrix can be derived independently from the consideration that the measured  $T$  matrix really does correspond to a homogeneous strain.

¶ Indices of an invariant plane and direction of motion of atoms.

§ Knowing the positions that poles of planes and directions in the austenite take after straining to martensite (this knowledge is based on the minimum displacement hypothesis of Jaswon and Wheeler<sup>4</sup> as well as the final orientation relationships), then it is possible to check the following requirements of the Bowles analysis: 1—initial and final positions of poles of planes that contain the direction of motion of atoms during one strain must lie on the same great circle as the pole of the invariant plane of the other strain, and 2—initial and final positions of directions lying in one of the invariant planes must lie on the same great circle as the direction of the motion of atoms during the other strain.

Fig. 3— $(111)_A$  projection of planes of no distortion and no rotation and corresponding habit planes.

pendix III. It is found that one and only one invariant plane is associated with a given  $T$  matrix, and that this unique invariant plane is closely parallel to the independently measured habit plane associated with the given  $T$  matrix.†† The excellent correlation between such experimental habit planes and their respective calculated invariant planes is shown in Fig. 3. The directions of atom motions for the  $T$  matrices are given stereographically in Fig. 4. Roughly these directions have the indices  $\langle 156 \rangle_A$ . In each permutation, the direction of motion does not lie in the invariant plane, and hence the first strain is not a simple shear.

Using the matrix method, the elements‡‡‡ of the second strain can be calculated from a knowledge of the first strain and the final orientation of the martensite relative to the austenite. It is assumed that the atoms move to the nearest set of proper positions in the oriented martensite lattice after the first strain.<sup>4</sup> This calculation is performed in Appendix IV. The results are shown in Fig. 5 for the case where the  $(259)_A$  permutation is the invariant plane of the first strain. The invariant plane of the second strain is close to  $(235)_M$  and the corresponding direction of motion is  $[11\bar{1}]_M$ . This direction lies in the second invariant plane, and hence the second strain is truly a shear. The elements of the first and second strains are summarized in Table II.

If the above analysis is consistent with the Bowles double-strain analysis, then the assumption of a pair of elements for either one of the strains should yield the pair of elements for the other strain using Bowles' stereographic treatments.§ Figs. 6 and 7 show that, starting with either pair of elements given in Table II, the other pair of elements can be obtained

Table II. Elements of Strains for Martensitic Transformations having  $(259)_A$  Habit

|                          | First Strain               | Second Strain   |
|--------------------------|----------------------------|-----------------|
| Invariant plane          | $(259)_A$ within $2^\circ$ | $(235)_M$       |
| Direction of atom motion | $[156]_A$ within $2^\circ$ | $[11\bar{1}]_M$ |

Fig. 5—Stereographic solution showing elements of second strain corresponding to (259)<sub>A</sub> habit plane.

from Bowles' stereographic method. It is interesting to note that the first invariant plane in Fig. 6 lies somewhat closer to  $(9\ 22\ 33)_A$  than to  $(259)_A$ . In evaluating these findings, it should be remembered that the probability of securing such consistent results from random choices of pairs of elements is virtually nil. From the correlation between the matrix analysis of the measured strain and the Bowles analysis, it may be concluded that the measured strain is actually homogeneous, otherwise the Bowles analysis would not yield the correct elements of the measured strain.

The matrix analysis also makes it possible to determine the succession of strains in the Bowles analysis. The sequence test performed in Appendix V demonstrates that the two strains must occur in the order already given in Table II. It is shown in Appendix V that the two strains are not commutative: if  $C$  is the final strain achieved by application

§§ This fact can be checked as follows: choose one invariant plane such that its pole lies on the great circle connecting either  $(9\ 22\ 33)_A$  and  $(235)_M$  for the  $\{259\}$  case or  $(225)_A$  and  $(112)_M$  for the  $\{225\}$  case. Choose one direction such that it lies on the great circle connecting  $[156]_A$  and  $[111]_M$  for the  $\{259\}$  case or  $[112]_A$  and  $[111]_M$  for the  $\{225\}$  case. This choice of a pair of elements will then determine the other pair of elements having internal consistency with the Bowles analysis, yet will not be the solution experimentally obtained.

Fig. 6—Stereographic analysis of plane transformations.

**Initial and final positions of poles of planes that contain the direction of atom motion during one strain lie on the same great circle as the pole of the invariant plane of the other strain.**

Initial and final positions of directions lying in one of the invariant planes lie on the same great circle as the direction of atom motion during the other strain.

of A followed by B, then application of B followed by A does not result in C. Thus, the correct orientation relation cannot be attained except by the proper sequence of the invariant-plane strains in Table II.

All the results described here hold, in principle, for the  $\{225\}_A$  as well as for the  $\{259\}_A$  systems.

## Discussion of Results

*Implications of the Bowles Analysis:* The question may now be raised as to the uniqueness of the solutions obtained using the Bowles double-strain analysis: that is, does a knowledge only of the orientation relationship between the austenite and martensite lattices and their structures permit a unique prediction of the elements of the two invariant-plane strains? Consideration of this problem leads to the conclusion that the Bowles double-strain analysis, of itself, does not yield a unique pair of invariant-plane strains.<sup>§§</sup> Some additional condition is required to make the solution unique. This condition is, according to the reaction-path concept of the martensitic transformation, that the first strain involving the minimum activation energy, whether it can be predicted a priori or not, is the one that actually operates. Then, the Bowles analysis, on the basis of the final orientation relations, will predict

a unique set of elements for the second invariant-plane strain. Theoretically, if the potential energy curve as a function of the strain for each possible first strain was known, then a unique pair of invariant-plane strains, and thus their elements, could be predicted.

From the observation that the atom motion in the second strain takes place along the only direction that remains close-packed in the unrotated, but distorted  $(111)_A$  plane after the first strain, for both the  $\{225\}_A$  case and  $\{259\}_A$  case, tentative criteria for predicting the unique invariant plane of the first strain (and hence the habit plane) can be set up using the Bowles stereographic analysis and the final orientation relationship between the austenitic and martensitic structures. Of the two close-packed directions in the  $(101)_M$  plane, the direction of motion in the second strain is selected as the one which makes the smaller angle with its original close-packed  $\langle 110 \rangle_A$  direction in the  $(111)_A$  plane. Thus, poles of planes in the zone of this direction must lie on the same great circle as the pole of the invariant plane of the first strain. By choosing this direction as the second direction of atom motion in the Bowles analysis, a unique prediction for the habit plane is obtained. This procedure might be termed a modified Bowles method.

The foregoing criterion for the habit-plane prediction suggests that different orientation relations will predict different habit-plane indices. In particular, the Kurdjumow-Sachs orientation predicts the  $\{225\}_A$  set of habit plane indices, the Greninger-Troiano orientation predicts the  $\{259\}_A$  set, and the Nishiyama orientation predicts a  $\{5\ 34\ 46\}_A$  set. It should be emphasized that the above criterion for prediction of the habit plane does not mean that the habit plane is controlled physically by the final orientation relationship, rather the reverse is implied: that is, the first strain corresponding to the minimum activation energy path will, according to the criterion, uniquely determine the final orientation relationship as well as the habit plane.

**Significance of Correlation between the Habit Plane and the Invariant Plane of the First Strain:** It has now been demonstrated that the double-strain mechanism of martensite formation in ferrous alloys can lead to a plane of no distortion and no rotation in the first strain lying close to the  $\{259\}_A$  habit when the Greninger-Troiano orientation prevails, and lying close to the  $\{225\}_A$  habit when the Kurdjumow-Sachs orientation prevails. These findings strongly suggest that the double-strain mechanism is real, and that the correlation of the habit plane with the first invariant plane is most significant.

There are two possible explanations for this correlation. The first explanation, as indicated by Bowles,<sup>5</sup> assumes the existence of a two-dimensional nucleus lying along the habit plane, having roughly the final radial dimensions of the plate to form. In this picture, the plate grows in thickness in such a way as to maintain the plane of the habit as an invariant plane of the first strain.

The second explanation is based on the very reasonable assumption that the martensitic embryo is quite small compared to the final martensitic plate. Thus, it is necessary to account for the preferential propagation of the transformation along the invari-

Fig. 8—Illustration of the effect of plate orientation, with respect to the invariant plane of the first strain, on strain energy.

$\gamma_0$  is the unit shear strain and  $w_0$  is the unit normal strain relative to the invariant plane. Note that if  $h \gg w$ , the displacements in the austenite surrounding the plate are smallest when the plate lies parallel to the invariant plane.

ant plane of the first strain. This result follows directly from a consideration of the strain energy developed in the austenite by a platelike region with different orientations of the plate relative to the invariant plane, as illustrated in Fig. 8. The plate has length and width dimensions  $w$ , thickness  $h$ ,

and  $\frac{w}{h}$  is taken equal to 10. From the assumption

that the stress developed at any point is proportional to the displacement of that point, and that the displacement is determined by the first strain only, the strain energy developed in the austenite for the plate lying parallel to the invariant plane turns out to be only 1/50 that for the plate lying normal to the invariant plane. Therefore, it can be concluded that as the first strain spreads out radially from the small embryo, the largest resistance is first encountered in the thickness direction. This resistance to the propagation of strain soon reaches a sufficient magnitude to limit further growth in thickness, probably by the onset of plastic flow.<sup>7</sup> The propagation of the strain along the invariant plane is relatively unhindered, and hence the plate spreads outward from the embryo mainly along the invariant plane of the first strain. The habit plane, as a result, lies parallel to the invariant plane of the first strain.

There are two implications in the latter basis for the choice of the habit plane. 1—Inasmuch as the invariant plane in this Fe-Ni alloy invariably belongs to the  $\{259\}_A$  family, then there must be a unique crystallographic first strain that is preferred to all other possible strains (such a unique crystallographic first strain is found experimentally as

Fig. 9—Pictorial representation of propagation of first and second strain through lattice along or normal to invariant plane.

§§§ The Jaswon and Wheeler direction-transformation matrix is used for making this selection.

Fig. 10—Martensite plates in a 1.1 pct C, 5.4 pct Ni steel.

Transverse markings on plates appear to be the traces of the invariant planes of the second strain. X1500. Taken by W. J. Harris, Jr., M.I.T., 1948.

shown in Appendix I) and this is synonymous with a unique initial portion of a reaction path.<sup>8</sup> It is readily understandable that one reaction path would be preferred to others because the activation energy along one path is the least of all possible paths. This is the one that operates during the first strain.<sup>¶</sup> 2—The other implication of the “least resistance” basis for the choice of the habit plane is that the second strain does not contribute materially to the strain energy developed in the austenite during the time interval when the habit plane is being determined. Otherwise the strain energy would not be a minimum for a plate lying along the invariant plane of the first strain. Thus, either the homogeneous portion of the second strain must be limited to extremely small volumes so as not to affect appreciably the elastic strain energy in the surrounding austenite, or the second strain occurs after the first strain has been completed throughout the entire platelike region. The latter alternative seems improbable. The first possibility is consistent with the requirement derived from the strain measurements, that the second strain must be macroscopically heterogeneous in order not to influence the observed strains.

The mode of plate formation described as the propagation of a transformation strain outward from an embryo can be explained in terms of Fig. 9. The strain wave starts to move when the strain in the

embryo just exceeds the critical strain for nucleation. The strain at the embryo then increases as the wave front of the first strain moves away from the embryo. When the magnitude of the first strain at the embryo reaches its final value, the second strain commences. At this time, the wave front of first strain has shifted to a position somewhat removed from the strain embryo. Hence, there exists a phase lag between the wave front of the first strain and that of the second strain. After the wave front of the first strain is stopped at a barrier, the wave front of second strain catches up with it to complete the formation of a martensite plate. This model of plate formation implies that the interface region between the austenite and the martensite during formation is thicker than one atomic spacing. Bowles' model involves the addition of one plane of atoms at a time, and neglects the gradient of second strain up to and beyond the moving interface.

*Double-Strain Nature of the Martensitic Transformation:* From the fact that the habit-plane predictions of the modified Bowles method are successful, and that the invariant-plane strains must have the proper sequence to yield the correct result, it may be concluded that at any point in the transforming region the reaction actually takes place by the operation of two successive strains in point of time.<sup>¶¶</sup> This situation makes it most unlikely that the plate formation could occur via atom-by-atom diffusion across a sharp interface.<sup>9, 10</sup>

Further evidence for the double-strain mechanism is shown in Fig. 10. The subbands within the martensite are brought out by tempering an Fe-Ni-C alloy. In the case of a  $(225)_A$  habit, the structure developed by the first strain is altered during the second strain by a shear of  $(112)_M$  planes in opposite directions  $(11\bar{1})_M$  and  $(\bar{1}\bar{1}1)_M$  to form twin-bands of the martensitic structure in two variants of the Kurdjumow-Sachs orientation.<sup>¶¶¶</sup> A similar picture holds for the  $(259)_A$  habit except that unequal amounts of shear are required and the final orientations are two variants of the Greninger-Troiano set. It is believed that on tempering the carbides tend to precipitate preferentially along these twin-like boundaries, as in Fig. 10, to delineate the banded structure. Hence these subbands provide indepen-

Fig. 11—Martensite plates in a medium carbon steel.

Habit plane indices are  $\{225\}_A$  and the plane of the paper is approximately  $(111)_A$ . After Greninger and Troiano.<sup>1</sup>

<sup>¶</sup> The presence of  $\{225\}$  habits as well as  $\{259\}$  habits in the same alloy system<sup>2</sup> implies the existence of two alternate reaction paths having almost the same activation energy.

<sup>¶¶</sup> There is no necessity so far to require each of these strains to be achieved by straight line motions.

<sup>¶¶¶</sup> This feature of the double-strain hypothesis is very satisfying intuitively. The first strain produces an unstable structure that is symmetrical with respect to the formation of pairs of twins through motions of  $(112)_M$  planes in the same or opposite directions. This situation does not exist until the first strain has been achieved.

dent evidence for the occurrence of a second strain that is macroscopically heterogeneous.

**Cooperative Formation of Martensitic Plates:** Because the second strain is macroscopically heterogeneous, the direction of motion of the austenite adjacent to the sides of a martensitic plate is given by the direction of motion of the atoms during the first strain. A study of the directions of motion for all the possible permutations of the  $\{259\}_A$  habit shows that there are four directions of motion lying on a cone of approximately a  $10^\circ$  half-angle about any  $\langle 110 \rangle_A$  direction; there are also six motion directions lying within a  $28^\circ$  half-angle cone about any  $\langle 111 \rangle_A$ , eight motion directions lying within a  $42^\circ$  half-angle cone about any  $\langle 100 \rangle_A$ , and twelve motion directions lying within a  $43^\circ$  half-angle cone about any  $\langle 111 \rangle_A$ . An analogous study of the directions of motion for all the possible permutations of the  $\{225\}_A$  habit indicates that there are three motion directions on a  $20^\circ$  half-angle cone about any  $\langle 111 \rangle_A$  direction; there are also four motion directions on a  $30^\circ$  half-angle cone about any  $\langle 110 \rangle_A$ , four motion directions on a  $35^\circ$  half-angle cone about any  $\langle 100 \rangle_A$ , and six motion directions within a  $55^\circ$  half-angle cone about any  $\langle 110 \rangle_A$ .

It may be expected that the strain energy per unit thickness of plate generated by the formation of plates adjoining the same austenitic region will be less if the plates tend to move the intervening austenite in the same direction rather than in opposing directions. In other words, a cooperative action in the martensitic transformation of many plates is predicted if their almost simultaneous appearance helps minimize the resisting strain energy. A rough measure of this cooperation is the number of "common" directions of motion in the first strain, and a comparison of the  $\{259\}_A$  and  $\{225\}_A$  habits shows that the degree of cooperation expected in the former is about twice that in the latter. The fact that there are twice as many  $\{259\}_A$  planes as  $\{225\}_A$  planes leads to a similar conclusion.

Pictorial evidence for this measure of cooperation is given in Figs. 11 and 12. Fig. 11, taken from ref. 1, shows a  $(111)_A$  plane in a medium carbon steel having a  $\{225\}_A$  habit. The triangular configurations of martensitic plates correspond to the three  $\{225\}_A$  poles lying on about a  $20^\circ$  half-angle cone around the  $[111]_A$  direction. This is the most preferred grouping of plates in the  $\{225\}_A$  system according to the above concept of cooperative movements. Fig. 12 shows two  $\{259\}$  type plates; specifically the habit planes are  $(5\bar{9}2)_A$  and  $(952)_A$  where the plane of the page is  $(111)_A$ . The common direction of motion (the half angle is about  $10^\circ$ ) is  $[110]_A$ . This is one of the two most preferred groupings for the  $\{259\}_A$  habit systems according to the above criterion of cooperation.

These concepts receive further confirmation in that they account for the observation of Greninger and Troiano<sup>1</sup> regarding the tendency for  $\{225\}_A$  systems to show obtuse angles between pairs of adjoining plates, whereas the  $\{259\}_A$  systems are characterized by acute angles between such pairs of plates. It turns out that a random section through the  $\{225\}_A$  grouping in Fig. 11 will exhibit obtuse angles, while a random section through the  $\{259\}_A$  grouping in Fig. 12 will exhibit acute angles.

**Twinning and the Martensitic Transformation:** Bowles<sup>5</sup> describes the elements of the two strains in the  $\{225\}_A$  system as close to those of twinning in

Fig. 12—Martensite plates in a 70 pct Fe-30 pct Ni alloy. Habit plane indices are  $\{259\}_A$  and the plane of the paper is  $(111)_A$ . X500.

the austenite and martensite respectively. In this study, it is found that the first strain has nothing in common with the twinning crystallography of austenite, whereas the second strain involves an approximation of the twinning elements for the martensitic phase. The second invariant plane is about  $5^\circ$  from the twinning plane of martensite, while the direction of atom motion is the same as in twinning.

Reinvestigation of the results of Bowles as well as those of Greninger and Troiano<sup>8</sup> discloses that the first direction of motion is in the anti-twinning direction. Thus the first strain of the Bowles  $\{225\}_A$  solution is not one of twinning in the austenitic phase. The second strain for the  $\{225\}_A$  case involves exactly the twinning elements of the martensitic phase. These facts lend credence to the conclusion that the second strain follows the first in any unit of volume undergoing the transformation. The first strain can be said to involve the most favorable reaction path for the transformation in the austenitic structure. The second strain involves the most favorable reaction path in the martensitic structure for the final position along the first strain. Indeed, it now appears that the final position along the first strain is a result of the intercession of a change in the reaction path (the second strain) which is more favorable than a continuation of the first strain.

**Magnitude of Strains:** It is interesting to note that the magnitudes of the strains associated with the transformation are much larger than elastic strains. For example, the component of strain normal to the invariant plane of the first strain is about 0.05, and the shear component is about 0.20; whereas the respective values for the second strain are 0 and 0.16. Because of the large stresses that must be associated with the normal component of strain during the first strain (the resisting stresses are compressional), it is likely that hydrostatic components of stress would affect the course of the transformation. This prediction, which was pointed out by S. A. Kulin, was recently confirmed by him at M.I.T.

**Evaluation of Theories Describing the Formation of Martensitic Plates:** There are at least three theoretical descriptions of the formation of a martensitic plate. One can be described as an atom-by-atom diffusion growth under the influence of coherency.<sup>9, 10</sup> Another is the mechanism described by

Fig. 13—Relationships between components of  $T$  matrix and coordinate-transformation matrix  $A$ .

Bowles as the growth by addition of one plane of atoms at a time. Still another is the wave-propagation method described in this paper.

The fact that the measured strain does not yield the martensite lattice, and the probable physical existence of the second strain heterogeneously distributed over the macroscopic plate, both testify against the likelihood of atom-by-atom movements. The requirement of succession in order of application of the two strains and the fact that the measured strain is a consistent invariant-plane strain also point up the improbability of atom-by-atom growth. Furthermore, the diffusion growth process does not seem to be a useful mechanism for the martensitic transformation from the standpoint of interpreting the crystallography involved.

With regard to the second mechanism, the  $\{259\}_A$  planes rotate during the second strain, and this means that a plate cannot grow by addition of one  $\{259\}_A$  plane at a time, with rotation of the  $\{259\}_A$  plane on the martensite side of the interface and no rotation of the  $\{259\}_A$  plane on the other side. Also, the requirement in this theory for a plate nucleus of almost final plate length and width lying along the  $\{259\}_A$  plane makes the Bowles plane addition mechanism highly improbable.

The remaining mechanism based on the propagation of the transformation strain as a wave has been shown to be a reasonable one in the text of this paper. Of the three mechanisms, it is the only one that yields consistent explanations for the known facts.

### Summary and Conclusions

1—All measured transformation strains for the austenite-martensite reaction are crystallographically equivalent in a given habit system. This suggests that, in general, only one reaction path operates in a given habit system.

2—The measured strain does not produce the martensite lattice from the austenite lattice. However, a sequence of two strains can generate the martensite in the correct orientation with respect to the austenite.

3—Each of these two strains can be described as

a homogeneous strain involving the motion of an invariant plane, i.e., a plane of no rotation and no distortion. The second strain is (close to) a simple shear, while the first strain is not. The second strain is homogeneous only over small regions compared to the volume of the martensitic plate.

4—The two strains obtained are consistent with the Bowles double-strain analysis for the  $\{259\}_A$  as well as the  $\{225\}_A$  habit systems. The measured strain is one of the Bowles strains and is therefore a homogeneous, invariant-plane type of strain.

5—From the latter result and the matrix analysis, it is deduced that there is a sequence to the operation of the strains in  $\{259\}_A$  systems as follows:

|                          | First Strain<br>(Measured Strain) | Second Strain |
|--------------------------|-----------------------------------|---------------|
| Invariant plane          | $(259)_A$ within $2^\circ$        | $(235)_M$     |
| Direction of atom motion | $[156]_A$ within $2^\circ$        | $[111]_M$     |

6—The observed habit plane lies parallel to, and is determined by, the invariant plane of the first strain. The parallelism helps minimize the strain energy developed during the formation of the plate.

7—The Bowles invariant-type, double-strain analysis does not yield a unique prediction for the habit plane. However, this prediction becomes possible when the following additional principle is introduced. The second direction of atom motion lies along the only remaining close-packed direction in the unrotated close-packed plane after the first strain.

8—The conclusion is reached that the Kurdjumow-Sachs orientations correspond to  $\{225\}_A$  habit planes and the Greninger-Troiano orientations correspond to  $\{259\}_A$  habit planes.

9—Metallographic evidence is shown for the existence of a macroscopically heterogeneous strain, corresponding to the predicted second strain.

10—The order of magnitude of the measured strain is quite large, about 0.1.

11—The martensitic transformation in  $\{259\}_A$  habit systems should be about twice as cooperative as in  $\{225\}_A$  habit systems. This follows from the fact that there are twice as many habit permutations in the former compared to the latter. Also there is a correspondingly greater tendency for groups of martensitic plates to move the intervening austenite in the same direction, thus minimizing the strain energy generated and allowing the plates formed to grow thicker than isolated plates.

12—The reaction-path description of the martensitic transformation is found to be more useful and more likely than the other proposed mechanisms.

#### Derivation of Relations between Measured $T$ Matrices and the Coordinate-Transformation Matrices

Suppose the coordinate-transformation matrix representing a certain strain is  $A$  where:

$$A = \begin{pmatrix} a_{xx} & a_{xy} & a_{xz} \\ a_{yx} & a_{yy} & a_{yz} \\ a_{zx} & a_{zy} & a_{zz} \end{pmatrix} \quad [A-1]$$

A point  $(x, 0, 0)$  is then transformed by this matrix to:

$$(x', y', z') = (a_{xx} x, a_{yx} x, a_{zx} x) \quad [A-2]$$

Now  $t_{yz}$  is the tangent of the angle between the  $X$  direction and the final position of this line projected onto the  $Z$  plane (Figs. 1 and 13). As shown in Fig. 13,  $t_{yz}$  is related to the components of  $A$  by the following equation:

$$t_{yz} = \frac{a_{yx} \cdot X}{a_{zx} \cdot X} = \frac{a_{yx}}{a_{zx}} \quad [A-3]$$

$$t_{zx} = \frac{a_{zx} \cdot X}{a_{xx} \cdot X} = \frac{a_{zx}}{a_{xx}} \quad [A-4]$$

By similarly investigating the transformation of points in the  $Y$  and  $Z$  axes, the following relations are obtained:

$$t_{xy} = \frac{a_{xy}}{a_{yy}} \quad t_{xz} = \frac{a_{xz}}{a_{zz}} \quad [A-5]$$

$$t_{zy} = \frac{a_{zy}}{a_{yy}} \quad t_{yx} = \frac{a_{yx}}{a_{xx}} \quad [A-6]$$

The diagonal components  $t_{xx}$ ,  $t_{yy}$ ,  $t_{zz}$  need not be discussed here because they are unnecessary to the analysis and have not been measured. They represent extensions or contractions and are difficult to determine.

**Calculation of Equivalence of  $T$  Matrices:** Because the  $Z$  axis is the  $[111]_A$  direction (Fig. 1), there exists a three-fold symmetry about this axis. Thus, a counter-clockwise and clockwise rotation by  $120^\circ$  should yield crystallographically equivalent matrices; that is, transformations in which the reaction path during the transformation is exactly the same.

In order to ascertain which of the  $T$  matrices are equivalent, values of the diagonal components are required. Such values have been approximated in Appendix III. It was found that  $T'_a$ ,  $T'_c$ , and  $T'_e$  are related to one another by  $120^\circ$  rotations about  $[111]_A$ , and similarly for  $T'_b$ ,  $T'_d$ ,  $T'_f$ . Furthermore, in investigating the relation between the single-prime matrices and the double-prime matrices, it was also found that any one single-prime matrix has a mirror symmetry with one of the double-prime matrices across a  $\{110\}_A$  plane. Thus, it may be concluded that all the matrices are crystallographically equivalent in that they represent the same crystallographic reaction path.

The best choice found for  $T'_a$  is:

$$\begin{pmatrix} 1.013 & 0.011 & \overline{0.03} \\ 0.10 & 1.079 & \overline{0.22} \\ 0 & 0 & 1 \end{pmatrix}$$

and for  $T'_b$  is:

$$\begin{pmatrix} 0.99 & 0.11 & \overline{0.16} \\ \overline{0.01} & 1.09 & \overline{0.14} \\ 0 & 0 & 1 \end{pmatrix}$$

## Appendix II

### Can a Body-Centered Cubic Structure be Obtained From the Measured Strain?

Inasmuch as the nondiagonal components of the  $T$  matrices (the only measured components) will yield the final positions of the axes (Fig. 1), the final angles between axes to determine whether the measured strain generates a body-centered cubic structure can be investigated.

From all the X-ray determinations of lattice orientations, it is found that at least one  $\{110\}_M$  plane is parallel to a  $\{111\}_A$  plane.\* From the work of Gren-

\* Actually, it can be deduced from the work of Greninger and Troiano that all close-packed planes in the austenite become  $\{110\}$  planes in the martensite.

\*\* It should be remembered in considering Fig. 14 that the original positions of the atoms are close-packed. This consideration places a limit on the possible choices of transformed directions corresponding to the original close-packed directions.

Fig. 14—Arrangements of atoms in  $(111)_A$  and  $(101)_M$  showing the three possible sets of choices of martensite directions derivable from  $[110]_A$  and  $[112]_A$ .

Note: Closed circles lie in next plane above plane of open circles.

inger and Troiano (Fig. 6 of ref. 4), it is also known that the pole of this  $\{111\}_A$  plane lies in the same octant on the stereographic projection as the pole of the habit plane. Using this knowledge and the fact that all the habit planes corresponding to the  $T$  matrices lie in the same octant as  $(111)_A$ , it may be concluded that  $(111)_A$  becomes  $(101)_M$ . This means that the final position of the  $(111)_A$  plane after the transformation is unrotated with respect to its initial orientation. In addition, the fact that  $t_{xx} = t_{yy} = 0$  shows that the  $(111)_A$  plane does not rotate during the first strain. Also, the fact that  $t_{xy} \neq 0$  and  $t_{yz} \neq 0$ , shows that the  $(111)_A$  is not the invariant plane of the first strain. Hence, the  $(111)_A$  must lie in the zone of the direction of motion of the invariant plane.

The next step is the determination of the angles between the deformed positions of the  $X$  and  $Y$  axes. According to the convention of sign, the final angle between the  $X$  and  $Y$  axes, providing  $t_{xx} = t_{yy} = 0$ , is:

$$90^\circ - \tan^{-1} t_{yz} - \tan^{-1} t_{xy}$$

Inasmuch as  $t_{xx} = t_{yy} = 0$  for all the  $T$  matrices, this angle can be calculated and for  $T'_a$  is:

$$90^\circ - \tan^{-1} 0.01 - \tan^{-1} 0.10 = 83^\circ 40'$$

There exists an experimental uncertainty in both  $t_{xy}$  and  $t_{yz}$ . Taking the extremes, the uncertainty in this transformed angle is about  $\pm 1^\circ 30'$ .

Reference to Fig. 14 shows that the most probable choices of angles for this "deformed" angle in the final body-centered cubic martensite are  $90^\circ$ ,  $70^\circ 32'$ , and  $109^\circ 28'$ .\*\* All these choices are out of the experimental range found ( $83^\circ 40' \pm 1^\circ 30'$ ) and hence it may be deduced that the structure corresponding to the measured strain is not martensite. Further calculations assuming the strain to be characterized by an invariant plane (Appendix III) shows unequivocally that the structure corresponding to the measured strain is not martensite.

## Appendix III

### Calculation of Invariant Planes and Directions of Atom Motion Corresponding to Measured $T$ Matrices

Now that the coordinate-transformation matrix has been related to the measured  $T$  matrix,  $A$  can be derived on the basis that in the transformation there exists at least one plane of no distortion and no rotation.

Let a set of coordinates be chosen in the following manner: The  $Z_1$  axis is taken perpendicular to this plane of no distortion and no rotation. Then consider the most general motion of this invariant plane; that is, motion in a direction not contained in the plane. The  $X_1$  axis is chosen to lie in the invariant plane and in the plane defined by the direction of motion and the  $Z_1$  axis. The  $Y_1$  axis defined by a right-handed set (as in Fig. 13) then lies in the invariant plane. Relative to these coordinates the most general coordinate transformation matrix which leaves the  $X_1Y_1$  plane undistorted and unrotated is:

Fig. 15—Positions of coordinate axes and rotations used to illustrate matrix analysis for determining the experimental first invariant plane and direction of atom motion.

$$A_1 = \begin{pmatrix} 1 & 0 & m \\ 0 & 1 & 0 \\ 0 & 0 & 1+n \end{pmatrix} \quad [A-7]$$

To show that this matrix has the properties claimed for it, operate with this matrix on any  $X_1Y_1$  plane, i.e.  $z = c$ :

$$\begin{pmatrix} x_1' \\ y_1' \\ z_1' \end{pmatrix} = \begin{pmatrix} 1 & 0 & m \\ 0 & 1 & 0 \\ 0 & 0 & 1+n \end{pmatrix} \begin{pmatrix} x_1 \\ y_1 \\ c \end{pmatrix} \quad [A-8]$$

or:

$$\begin{aligned} x_1' &= x_1 + cm \\ y_1' &= y_1 \\ z_1' &= c(1+n) \end{aligned}$$

Thus, the plane at  $z_1 = c$  is carried into a plane parallel to itself at  $z_1 = c(1+n)$ . Further, it can be proved that distances and angles in the plane are preserved. Hence, the  $X_1Y_1$  plane is an invariant plane.

Now, however, the matrix  $A_1$  must be converted into an equivalent matrix in the coordinate system used in the measurements because the  $X_1Y_1Z_1$  axes are arbitrary in these considerations. This calculation can be performed either step-wise or in one operation. Inasmuch as it is easier to visualize the resulting quantities from the step-wise calculation, the discussion will be from this point of view.

The equivalent matrix  $A_4$  in the coordinate system used for the measurements can be derived from  $A_1$  by a series of three rotations as described in Fig. 15, namely,  $R_{r,s}$ ;  $R_{f,g}$  and  $R_{p,q}$ . The subscripts in the above are respectively the cosine and sine between the axes shown for the respective rotations. Using matrix algebra, the equivalent matrix is obtained as follows:

$$\begin{aligned} A_4 &= R_{p,q}^{-1} R_{f,g}^{-1} R_{r,s}^{-1} A_1 R_{r,s} R_{f,g} R_{p,q} \\ &= \begin{pmatrix} 1 + p^2n + pqgms & -pqn - q^2gms & pmr - qfms \\ -pqn + p^2gms & 1 + q^2n - pqgms & -qmr - pfms \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} a_{xx} & a_{xy} & a_{xz} \\ a_{yx} & a_{yy} & a_{yz} \\ a_{zx} & a_{zy} & a_{zz} \end{pmatrix} \end{aligned} \quad [A-9]$$

As shown by eq A-9 there are certain relations between the derived experimental quantities  $a_{ij}$  and the components of  $A_4$ . These relations make the determination of the invariant plane possible and are:

$$-\frac{p}{q} = \frac{a_{yx} a_{xz}}{a_{xy} a_{yz}} \quad [A-10]$$

$$\frac{g}{f} = \frac{a_{xy} - a_{yz}}{qa_{xz} + pa_{yz}} \quad [A-11]$$

$$n = -\left(\frac{p}{q} a_{xy} + \frac{q}{p} a_{yz}\right) \quad [A-12]$$

Fig. 16—Motion of atoms of primitive tetrahedral cell of austenite during transformation to martensite.

Motions lie in plane of paper which is  $(111)_A \parallel (101)_M$ . Atom No. 3 lies in plane above the plane containing atoms No. 0, 1, and 2.

$$\frac{r}{s} = -\frac{fn}{a_{yx} - a_{xy}} \quad [A-13]$$

and

$$m = -\frac{fn}{gr} \quad [A-14]$$

Because the diagonal components  $t_{xx}$ ,  $t_{yy}$ ,  $t_{zz}$  have not been measured, it is necessary to use an approximation method to obtain the values of the components of  $A_4$  as follows:

1—Assume  $a_{ij} = t_{ij}$  and calculate values of  $p$ ,  $q$ ,  $f$ ,  $g$ ; ( $gms$ ) and  $n$  using eqs A-10 to A-14.

2—With these tentative values of cosines and sines, calculate first approximations of the diagonal components  $a_{xx}$ ,  $a_{yy}$ ,  $a_{zz}$  using eq A-9.

3—Using these values of the diagonal components, recalculate the second approximations of the nondiagonal components and repeat steps 1 to 3 until the computed values of  $a_{ij}$  do not change measurably with further approximations.

It was found that the second approximations of  $a_{ij}$  were sufficient since rapid convergence existed.

The second-approximation solutions corresponding to  $T_a'$  and  $T_b''$  are:

|         | $p/q$  | $g/f$       | $r/s$       |
|---------|--------|-------------|-------------|
| $T_a'$  | -1.29  | $\pm 0.581$ | $\pm 0.878$ |
| $T_b''$ | +0.100 | $\pm 0.685$ | $\pm 0.61$  |

In using these values, care must be taken to be consistent in sign for any particular choice of sign of  $p$  and  $f$ . Otherwise the solutions are liable to result in rotations in the wrong directions.

On carrying through the calculated rotations for the solutions to  $T_a'$ ,  $T_b''$ , and their crystallographic equivalents, the results shown in Figs. 3 and 4 are obtained.

## Appendix IV

### Calculation of Elements of Second Strain

The elements of the second strain can be determined by the following procedure:

1—Calculate the positions of the atoms defining the primitive tetrahedral cell in austenite after the first strain relative to the austenite lattice.

2—Pick the orientation of the martensite lattice relative to the austenite and transform the positions found in 1 to be relative to the martensite axes.

3—Select the nearest positions of these atoms that would correspond to the martensite structure.

4—Calculate the coordinate transformation matrix required to transform the atoms from the positions found in 2 to their respective positions chosen in 3.

5—Analyze this matrix according to the method outlined in Appendix III.

Carrying through this procedure using  $T_c'$  to determine the positions of the atoms after the first strain, the following results are obtained (Fig. 16):

| Atom | After First Strain                  |                                      |                                     |
|------|-------------------------------------|--------------------------------------|-------------------------------------|
|      | Position Relative to Austenite Axes | Position Relative to Martensite Axes | Nearest Atom Position in Martensite |
| (1)  | (0.113, 2.47, 0)                    | (0, 2.475, 0)                        | (0, 2.477, 0)                       |
| (2)  | (2.36, 1.33, 0)                     | (2.42, 1.22, 0)                      | (2.34, 0.83, 0)                     |
| (3)  | (1.17, 1.44, 2.06)                  | (1.24, 1.39, 2.06)                   | (1.17, 1.65, 2.02)                  |

The matrix relating the atom positions after the first strain to those in the final martensite is found to be:

$$B = \begin{pmatrix} 0.96 & 0 & 0.0113 \\ 0.163 & 1 & 0.224 \\ 0 & 0 & 0.98 \end{pmatrix}^{***}$$

Solving this  $B$  matrix according to the method outlined in Appendix III yields the results given in Fig. 5 for the elements of the second invariant-plane strain. The  $B$  matrix corresponding to the second strain is also used in Appendix V to test for the sequence of strains.

## Appendix V

### Non-Commutability of First and Second Strains

If the first and second strains are commutable, i.e., interchangeable in their sequence, then  $AB = BA$ . Checking with the  $T_c'$  case as an example:

$$AB = \begin{pmatrix} 1.109 & 0.045 & 0.205 \\ 0.045 & 0.980 & 0.084 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0.96 & 0 & 0.0113 \\ 0.163 & 1 & 0.224 \\ 0 & 0 & 0.98 \end{pmatrix}$$

$$AB = \begin{pmatrix} 1.070 & 0.045 & 0.199 \\ 0.117 & 0.980 & 0.138 \\ 0 & 0 & 0.98 \end{pmatrix} \quad [A-15]$$

\*\*\* The (zz) component has been taken as equal to 1 in finding the plane of invariance for this matrix. This corresponds to the approximation used by Bowles, namely that of neglecting the change in atom radius due to the change in coordination number.

$$BA = \begin{pmatrix} 1.063 & 0.043 & 0.186 \\ 0.136 & 0.987 & 0.173 \\ 0 & 0 & 0.98 \end{pmatrix} \quad [A-16]$$

Thus  $AB \neq BA$ , and the matrix multiplication is not commutative.

Because  $A$  and  $B$  are the invariant-plane solutions for the first and second strains, and the order of application of  $A$  followed by  $B$  (see Appendix IV) yields the correct final orientation, then this sequence must be followed physically.

## Technical Note

### Metallographic Techniques for Austenite Grain Size of Steels in the As-Cast State

by Edward A. Loria

A SERIES of papers on the study of austenite grain size in cast steels has been published recently.<sup>1-5</sup> These studies show that in the as-cast state, the austenite grains are quite large, for they form as the steel freezes at a very high temperature, but a simple reheating above the critical range produces a new

set of austenite grains which, in many instances, is finer than ASTM grain size No. 8. Furthermore, there is no apparent relationship between as-cast austenite grain size and subsequent grain size produced by heat treatment.

The as-cast austenite grain size can be determined easily in plain carbon and low alloy steels which produce a continuous grain boundary ferrite envelope in the as-cast structure. In the case of cast steels whose alloy content produces greater hardenability and suppresses the proeutectoid ferrite transforma-

E. A. LORIA, Member AIME, formerly Senior Fellow, Mellon Institute of Industrial Research, Pittsburgh, is now Senior Engineer, Metallurgy, The Carborundum Co., Niagara Falls, N. Y.  
TN 88E. Manuscript, July 13, 1951.

Fig. 1a—As-cast macrostructure of alloy cast steel containing 0.25 pct C, 1.05 pct Mn, 0.65 pct Ni, 0.61 pct Cr, and 0.22 pct Mo. Modified nitrosulphuric etch. X2. Area reduced approximately 20 pct for reproduction.

tion, there is no such indicator of the location of the original grain boundaries. Hence it becomes necessary to employ special etching reagents in order to bring out the structure. Perhaps some value for as-cast grain size determinations can be seen if consideration is given to the mechanism of diffusion and its relation to homogenization of structural components during heat treatment. Normally structural equilibrium is more rapidly attained with the smaller grain so that time of heat treatment required for homogenizing cast steels should normally decrease with decrease in austenitic grain size.

In a previous paper<sup>4</sup> the initial results on the use of a modified nitrosulphuric reagent in revealing the as-cast structure and grain size in a few cast alloy steels, which did not show ferrite outlining of the original grain boundaries, were shown. Such work has been continued in an effort to learn the quantitative effects of smaller initial grain size on homogenization of alloy cast steel. For this purpose the polished cross-sections of hardenability test bar castings have been subjected to the action of the modified nitrosulphuric reagent. Fig. 1a shows the excellent grain contrast that is produced across the 1½ in. diam bar of a popular grade of alloy cast steel. Such results can be obtained with this reagent when it consists of 20 ml concentrated nitric acid, 10 ml concentrated sulphuric acid, and 20 ml distilled water. The etching procedure was described previously.<sup>4</sup>

In steels exhibiting temper brittleness, it has been found that the addition of the wetting agent, Zephiran chloride, to a modified picral etch reveals a precipitate not shown by other etching reagents.<sup>5</sup> The excellent delineation of the grain outlines occurring in embrittled steel upon etching with the Zephiran reagent, particularly when the specimen is lightly repolished after etching, indicates that this agent would certainly assist in the search for the interfaces of as-cast grains. Therefore, 1 pct Zephiran chloride has been added to 4 pct nital and has increased the sensitivity of the latter and the speed of etching. Since the as-cast grains are quite large,

Fig. 1b—As-cast macrostructure of alloy cast steel containing 0.31 pct C, 1.44 pct Mn, 0.26 pct Mo. 6 pct nital-1 pct Zephiran chloride etch. X1.7. Area reduced approximately 20 pct for reproduction.

Fig. 1c—As-cast macrostructure of alloy cast steel containing 0.31 pct C, 1.44 pct Mn, 0.26 pct Mo. Modified nitrosulphuric etch. X2. Area reduced approximately 50 pct for reproduction.

a macroetch is really needed, and hence the best results have been obtained employing 1 pct Zephiran chloride in 6 pct nital. An example of the way this grain boundary etchant reveals the as-cast structure in conventional 1½x1¼ in. tensile test coupons of alloy cast steel is given in Fig. 1b. Each cross-section was immersed in the reagent until the grain boundaries became apparent visually. A comparison can be made with a similar sized coupon of the same alloy cast steel etched with the modified nitrosulphuric reagent and shown as Fig. 1c. Thus it can be seen that the modified nitrosulphuric reagent as a grain contrast etchant and the 6 pct nital-1 pct Zephiran chloride reagent as a grain boundary delineator are welcome additions to the tools available for the metallography of cast steels.

# Low Sulphur Steel from High Sulphur Raw Materials and Fuel

by F. L. Robertson, C. H. Bacon, and J. W. Till

A description is given of the development of a process for making low sulphur steel on furnaces fired with 2½ pct sulphur oil. Slag and metal are analyzed at melt. Slag weight is estimated. A simple method for calculating necessary lime additions for making 0.025 and 0.035 pct sulphur steel is given.

DURING the last 15 years John Summers & Sons have been confronted increasingly by the problem of producing a low sulphur steel from high sulphur materials. The principles adopted, the processes used, the data collected on a furnace specially set aside to study this problem, and speculation on future developments are dealt with in this paper.

This study is limited to two melting shops which make sheet steel only, of the following analysis: C, 0.06 pct; Mn, 0.33; S, 0.04, 0.035, 0.03, and 0.025; and P, 0.02 and 0.015. All the processes described have reference to the manufacturing of this steel and are not necessarily applicable, without modification, to other steels. The raw materials used are given in Table I.

## Development of Process

About 1934, Schenck's work on phosphorus was applied to frame quantitative rules for the removal of phosphorus, with great success. We could however, neither in our own work nor in the voluminous literature, find any assistance to frame quantitative furnace rules to remove sulphur. Perhaps, we should have persevered with Schenck's outstanding chapter on sulphur in *The Physical Chemistry of Steelmaking*, but we missed the importance of one

sentence on p. 478. "Evidently this ratio  $\frac{(\sum S)}{[S]}$  is

the important quantity to be considered from the point of view of chemical reaction; it is clear that the sulphur content of the steel alone, as frequently given in the literature cannot suffice for judging the success of the reaction unless special details are given regarding the sulphur charge and the amount of slag."<sup>1</sup> We were not however very successful in getting values for Schenck's "η" that agreed with

$\frac{(\sum S)}{[S]}$  arrived at by our direct analysis.

In addition to Schenck's work much attention was given to V value. The formula selected for V was:

$$V = \frac{(\sum \text{CaO}) - 1.57 (\sum \text{P}_2\text{O}_5)}{(\sum \text{SiO}_2)}$$

After plotting many charges a curve was obtained, based upon the relationship between the percentage

F. L. ROBERTSON, deceased. C. H. BACON and J. W. TILL are with John Summers & Sons Ltd., Hawarden Bridge Steelworks, Shotton, Chester, England.

Discussion on this paper, TP 3106C, may be sent, 2 copies, to AIME by Jan. 1, 1952. Manuscript, Feb. 26, 1951. St. Louis Meeting, February 1951.

sulphur in the finished steel and V value, Fig. 1. For a long time this was used as standard with about a 60 to 70 pct success on producer-gas fired furnaces, if all uprising scrap was used and no bought scrap used. An inspection of this curve shows clearly that it is not a quantitative manufacturing process, and that it was not sure enough to go to the trouble and expense of doing stage analysis for  $\text{P}_2\text{O}_5$ ,

Fig. 1—Relationship between percentage of sulphur in steel and V value for producer-gas fired furnaces. (Coal 1 pct S.)

Fig. 2—Carbon/temperature curve.

CaO, and SiO<sub>2</sub>. At this time there was no problem in making as much 0.025 pct S steel as required, and other matters pressed.

In 1946, four oil (S = 2.5 pct) fired furnaces were introduced and it was found that conditions that had given 60 to 70 pct of 0.025 pct S charges on producer gas firing gave none on oil firing. Generally throughout the works, this was ascribed to the sulphur in the oil but, even yet, this is not proven for certain until more quantitative work is done to insure that the slag weights are equal in both cases. The works position was, however, so serious that the whole question of sulphur passage between the slag and steel was studied anew.

By this time Grant and Chipman's paper had appeared.<sup>2</sup> With this, and with Schenck's older work as a basis, work was started with a view to evolving a process for making steel of any specified sulphur content from the materials available.

With the combined assistance from many departments and Trade Union organization in the Works, a scheme was set up to work one furnace under special supervision and controlled conditions.

*Experimental Furnace Trials:* The furnace was fully instrumented and was given priority in operation. The object was to reduce the variables to a minimum, so that the relation between furnace practice and rate of output could be studied. This presented an opportunity to study sulphur in a way that had not been possible before. A full report of the furnace conditions and their relation to output is given in a paper by Robertson and Thring.<sup>3</sup> A short description of the conditions of the trial, insofar as they influence the investigation on sulphur, will be presented here.

Three roof pyrometers are fitted and the oil flow is controlled automatically from them. The control system is arranged to operate so that, as soon as one of the three pyrometers reaches the set maximum temperature, the oil flow is reduced. A maximum fuel flow controller is incorporated to operate before the maximum roof temperature is reached.

The furnace is charged with 58 tons of steel scrap and about 31 tons of cold machine-cast pig iron. When possible, the scrap used for these trials was all uprising scrap, consisting of slab crops and sheet clippings, to enable an estimate of the analysis to be made.

The actual weight of pig iron needed to give a carbon of 0.3 to 0.5 pct, when clear melted, is calculated by means of the oxygen equivalent. The oxygen equivalent per ton of iron is the weight of oxygen required to oxidize the C, P, Mn, and Si in one ton of iron to CO, P<sub>2</sub>O<sub>5</sub>, MnO, and SiO<sub>2</sub>. The figure for the total oxygen equivalent is found by experience on the furnace and this figure, divided by the oxygen equivalent per ton, gives the weight of pig iron required.

A standard charging sequence was introduced and processing during refining was controlled. Fig. 2 shows the carbon temperature curve adopted. Feeding of lime and ore was not permitted until the steel temperature, obtained by an immersion pyrometer, reached the figure on the curve corresponding to the carbon in the steel. The time at which this occurs is referred to as "junction," instead of the more commonly used "melt out." Junction is defined in the measurable terms of carbon and temperature and therefore is considered to have more value in control work than melt out, which is not capable of precise definition.

Table I. Analysis of Raw Materials, Percent

| Material              | C       | Si      | Mn       | S         | P        |
|-----------------------|---------|---------|----------|-----------|----------|
| 33 pct cold pig       | 3.5-3.8 | 0.4-1.2 | 0.75-1.5 | 0.03-0.07 | 0.75-1.5 |
| 33 pct uprising scrap | 0.06    |         | 0.3      | 0.04      | 0.02     |
| 33 pct bought scrap   | 0.2     |         | 0.5      | 0.06      | 0.06     |
| Burnt lime            |         |         |          | 0.1-0.2   |          |
| Spar                  |         |         |          | 0.6-0.8   |          |
| Oil                   |         |         |          | 2.3-2.7   |          |
| Coal                  |         |         |          | 0.9-1.4   |          |

Fig. 3 is a copy of one of the master charts. The individual furnace charts are copied on to this chart, and the following data is shown: charging sequence, roof temperature, oil flow, steam flow, air flow, furnace pressure, CO<sub>2</sub> and O<sub>2</sub> in waste gas, steel temperature rise, and carbon, sulphur and manganese drop.

The ingoing materials in the form of pig iron, lime, spar and ore are analyzed. Full analyses are also carried out on the metal and slag at junction and tapping. The calculation sheet, Fig. 4, is our approach to the study of the behavior of the carbon, silicon, phosphorus, sulphur, and oxidation during the course of the charge and their distribution between the metal, slag, and furnace atmosphere. The top line in each case represents the percentage of the element present. The second line shows the weight of the element (all weights shown are in tons, except sulphur, which is in pounds. References to tons in this paper have been converted to short tons). The third line gives the weight of oxygen that will combine with the element, and the fourth line gives the weight of the oxide formed. The balances for the oxidation, sulphur, and silicon are shown on the right.

In the case of the sulphur balance, the weight of sulphur introduced through the pig iron and scrap is shown under "Metals," and from the lime and spar under "Nonmetals." The difference between the weight of sulphur in the system at junction and the weight of sulphur in the charge gives the weight of sulphur absorbed from, or lost to, the furnace atmosphere. Analysis of the tapping samples enables a second balance to be made showing the pick up or loss between junction and tapping, after making allowance for any sulphur introduced with the feeds.

This information is set out in a rather different form in Fig. 5. This flowsheet proved to be the most helpful approach to the study of the behavior of sulphur. The important points that emerged from the careful study of a large number of sulphur flowsheets were:

- 1—That the  $\frac{(S)}{[S]}$  value at junction varied greatly.
- 2—That the  $\frac{(S)}{[S]}$  value at tapping varied considerably, but that the bulk of the results were in excess of 6. Fig. 6 shows the range of  $\frac{(S)}{[S]}$  at tapping for 250 charges.
- 3—That the pickup of sulphur from the furnace atmosphere varied within wide limits, but that the average figures could be taken as 30 lb between start charge and junction and nil between junction and tapping.

Figs. 7 and 8 are histograms showing the spread

for these values. Further study of the results gradually led to the conclusion that an understanding of the behavior of sulphur between the liquid phases could not be reached, unless the weight of the slag and the weight of the steel and the total weight of the sulphur in each were taken into account, besides the percentage of sulphur in the steel and the percentage of sulphur in the slag.

The Partition law cannot be used as a foundation for an extraction process, unless the weights of the two liquid phases, together with the total weight of the substance to be extracted, are taken into account, besides the ratio of the percentage concentrations of the substance in the two liquid phases.

This fundamental principle of the proper application of the Partition law, so well and so long understood in other industries, had escaped, not only ourselves, but other workers in the field. Except for one sentence in Schenck, to which reference has been made, no reference has been found in steel sulphur literature to the fact that consideration of percentages of sulphur in slag and steel is not enough without the weights of steel and slag, and weights of sulphur in each.

At this point we wish to give our apologies to Donald E. Babcock for not acknowledging his work in The American Iron and Steel Institute Proceedings of May 1949.<sup>4</sup> We would explain that our process was worked out and in operation on all furnaces in November 1948. We even venture to regret that Mr. Babcock, who clearly agrees with us, has been tempted to assume a constant slag weight in many of his examples.

**Sulphur Partition  $\frac{(S)}{[S]}$**  : Most of the literature concerning sulphur in steel is confined to the distribution of sulphur between steel and slag as measured by:

$$\frac{\text{Pct Sulphur in Slag}}{\text{Pct Sulphur in Steel}}$$

Numerous formulas have been evolved giving different degrees of effect upon this partition ratio to the lime, magnesia, manganese, iron oxide, silica, and alumina contents of the slag. Several of these formulas have been tested and compared with the partition figure obtained by direct analysis of steel and slag for sulphur. For our class of steel, closer agreement has been found with Grant and Chipman's Excess Base figures than with any other formula that has been tried.

Fig. 9 is a copy from Grant and Chipman's paper showing the relation between the calculated Excess

Fig. 5—Sulphur flowsheet, cast L204.

Fig. 6—  $\frac{(S)}{[S]}$  at tapping, 250 charges.

Fig. 7—Sulphur gain. Start charge to junction. 250 charges.

Fig. 8—Sulphur gain. Junction to tap. 250 charges.

Base figure and  $\frac{(S)}{[S]}$  by analysis for steel and slag samples from open hearth furnaces. Fig. 10 shows the results for 50 of our charges plotted on the same scale. It will be observed that our results show a very similar pattern to the former with a tendency for the higher  $\frac{(S)}{[S]}$  plots to be rather above the standard line.

It is obvious that the higher the  $\frac{(S)}{[S]}$  that can be obtained at tapping, the lower will be the slag weight that need be carried for a given sulphur burden and a given desired sulphur percentage in the steel. So, any formula that will give an insight into the factors that are conducive to a high  $\frac{(S)}{[S]}$  is valuable as a guide to the slag composition that will give the best possible desulphurization of the metal. For a process which is based upon the calcula-

tion of the feed lime required for individual charges, however, it has not been regarded as feasible to predict the  $\frac{(S)}{[S]}$  for each charge by any basicity measurement. Therefore our process has been based upon an expected  $\frac{(S)}{[S]}$  of 6.0 at tapping. Frequently figures are obtained that are considerably in excess of 6, but the process must necessarily be based upon a figure rather below the mean, for safety.

*Basis for a Process:* At this juncture it became apparent that the basis for a process must consist in increasing the slag weight, so that, at tapping, the percentage of sulphur in the slag is 6 times the percentage of sulphur desired in the metal, and that a means must be found to express this quantitatively in terms of lime additions. A calculation to determine the slag weight necessary for specified sulphur percentage in the steel, in terms of total weight of sulphur in the system and  $\frac{(S)}{[S]}$  follows.

- $W$  = Weight of steel, lb
- $w$  = Weight of slag, lb
- $P$  = Percentage of slag weight of steel weight
- $[S]$  = Percentage of sulphur in steel
- $(S)$  = Percentage of sulphur in slag
- $TS$  = Total weight, lb, of sulphur in steel and slag
- $L$  = Weight of sulphur in steel, lb
- $TS - L$  = Weight of sulphur in slag, lb
- $A = \frac{\text{Pct Sulphur in Slag}}{\text{Pct Sulphur in Steel}}$

$$\begin{aligned} \text{Then } A &= \frac{(S)}{[S]} = \frac{\frac{(TS-L) \times 100}{w}}{\frac{L \times 100}{W}} \\ &= \frac{TS-L}{L} \times \frac{W}{w} \\ &= \left( \frac{TS}{L} - 1 \right) \times \frac{W}{w} \\ &= \left( \frac{TS}{L} - 1 \right) \times \frac{100}{P} \end{aligned}$$

$$\text{Therefore, } P = \frac{TS \times 100}{L \times A} - \frac{100}{A} \quad [\text{Eq 1}]$$

For 168,000 lb steel:

$$L = \frac{[S]}{100} \times 168,000 = 1680 \times [S]$$

$$\text{And } P = \frac{TS \times 100}{1680 \times [S] \times A} - \frac{100}{A} \quad [\text{Eq 2}]$$

And for  $\frac{(S)}{[S]} = 6.0$  and  $[S]$  0.025, 0.030, and 0.035, the calculations are given in the following table:

|                   | For 0.025 Pct Sulphur Steel                                        | For 0.030 Pct Sulphur Steel                                        | For 0.035 Pct Sulphur Steel                                        |
|-------------------|--------------------------------------------------------------------|--------------------------------------------------------------------|--------------------------------------------------------------------|
| Slag wt pct $P =$ | $\frac{TS \times 100}{1680 \times 0.025 \times 6} - \frac{100}{6}$ | $\frac{TS \times 100}{1680 \times 0.030 \times 6} - \frac{100}{6}$ | $\frac{TS \times 100}{1680 \times 0.035 \times 6} - \frac{100}{6}$ |
| Slag wt pct $P =$ | $\frac{TS}{2.52} - 16.7$                                           | $\frac{TS}{3.02} - 16.7$                                           | $\frac{TS}{3.52} - 16.7$ [Eq 3]                                    |

Fig. 9—Sulphur distribution in the basic open hearth. After Chipman and Grant.

Fig. 10—Sulphur distribution in the basic open hearth. 50 charges. After Chipman and Grant.

Figs. 11a, b, c, and d are charts based upon this calculation, showing the slag weights necessary for 0.025, 0.030, 0.035, and 0.040 pct sulphur steel for differing  $\frac{(S)}{[S]}$  values and pounds of sulphur in steel

and slag. Figs. 12a, b, c, and d are charts for  $\frac{(S)}{[S]}$  values of 4, 6, 8, and 10 showing the slag weights necessary for differing sulphur percentage in the steel and pounds of sulphur in steel and slag. At this stage it only remained to work out simple means to assess the weight of sulphur in steel and slag at junction, and the slag weight increase required between junction and tapping, in order to make the process straightforward enough to be adopted as standard shop practice. Fig. 13 shows the lime additions necessary for the desired slag weight increase.

*Slag Weight:* It can be seen that in order to work such a process, it is essential to be able to estimate the slag weight with reasonable accuracy. In our early work on the experimental furnace, the slag weights were based upon the percentage of phosphorus in the pig iron and the  $P_2O_5$  percentage in the slag. Calculations based upon manganese and lime were also used.

Fig. 11—Slag weight required vs. pounds of sulphur in steel and slag. Steel weight is 168,000 lb.  $\frac{(S)}{[S]}$  is 2.0 to 12.0.

Fig. 12—Slag weight vs. pounds of sulphur in steel and slag. Steel weight is 168,000 lb. Final  $[S]$  pct is 0.025, 0.030, 0.035, and 0.040.

Table II\* gives the result of a comparison of the slag weights obtained when calculated from  $P_2O_5$  and from lime. Also included in this table is the figure by which the final sulphur percentage in the steel would be affected by the error between the two figures for slag weight at junction. Though the actual difference in slag weight appears to be considerable in some cases, the effect upon the sulphur percentage in finished steel is relatively small, the

maximum difference is 0.006 pct S, the average absolute difference is less than 0.002 pct S.

Provided that the slag weight can be estimated to about  $\pm 2$  tons, the process can be worked satisfactorily. The slag weight obtained by lime gives results within these limits and has been adopted as a basis for shop practice.

The simple shop rule has been adopted of doubling the weight of lime charged to obtain the slag weight at junction. Fluxing from the banks in this period is not severe and can be ignored. After junction, the bank erosion is severe and is dependent upon the duration of the refining time. Allowance can be

\* For Tables II and IV order Document 3361 from American Documentation Institute, 1719 N Street, N.W., Washington 6, D. C., remitting \$1.00 for microfilm (images 1 in. high on standard 35 mm motion picture film) or \$1.00 for photocopies (6x8 in.) readable without optical aid.

Fig. 13—Lime feed vs. required increase in slag weight.

Furnace capacity is 168,000 lb. Allowance is made for the lime fluxed from the bottom, which is related to the time from junction to tapping. The carbon at junction is used as a measure of the latter.

made for this in calculating the lime addition as shown in Fig. 13 by means of introducing the factor of carbon percentage at junction.

**Rules for Making Steel of a Specified S Content:** The following represent the rules for shop practice reduced to the simplest possible terms:

1—Calculate the weight of pig iron in the charge to give a carbon of 0.3 to 0.5 at junction. This calculation is based on the oxygen equivalent per ton of pig iron as explained for experimental furnace.

2—Calculate the amount of lime to be charged to give a  $V$  value of approximately 4 at junction.

3—Weigh the lime charged to within  $\pm \frac{1}{2}$  ton.

4—Analyze the metal and slag for sulphur at junction and calculate the total weight of sulphur in pounds, assuming the slag weight to be twice that of the lime charged.

5—Calculate the required lime addition from the chart or calculation wheel to give the desired sulphur content at tapping with  $\frac{(S)}{[S]}$  of 6. The maxi-

mum amount of lime that can be fed economically is found by experience. If the weight calculated for the desired sulphur percentage in the steel exceeds this figure, it is advisable to schedule the steel for a higher sulphur percentage and re-calculate the lime required on the new figure.

6—When the carbon is down, the lime in solution, and the temperature 2895° to 2930°F, check the

steel for sulphur percentage and tap the furnace.

**Calculation Wheel:** Fig. 14 shows the calculation wheel for 0.035 pct sulphur steel, and one of these is fitted on to each furnace. From the steel and slag analysis at junction, the weight of sulphur in pounds in each is obtained. From the sum of these, the amount of feed lime required to give 0.035 pct sulphur in the finished steel is read off. This is given in terms of number of barges, each barge being equivalent to 12 cwt (1350 lb) of lime.

Fig. 15 shows a refinement, by which the weights of lime feed required for 0.025, 0.030, and 0.035 pct sulphur steel can be obtained directly from the percentage of sulphur in steel and slag at junction. It must be stressed that the calculation wheel is only applicable for a standard weight of charged lime. A constant weight of 4.7 tons of lime is now used for charges made with the normal supply of pig iron.

**Process in Operation:** It is now 27 months since the process was put into operation on all furnaces in the two shops, and over a million tons of steel have been made during this time. The process is welcomed by the melting shop. All sulphur grades can be made without concern, with scrap, as it comes, either on the oil-fired or gas-fired furnaces. Output has gone up and not down, since its introduction.

It has been said that the process is not accurate enough. It is, therefore, worth looking into the accuracy, to which the shop has to work.

The melting shop manager, ordered to make 0.025 pct sulphur steel, is not held to account if his steel ranges from 0.022 to 0.027 pct.

Fig. 16a, b, c, and d show the effect of errors in slag weight at tapping or  $\frac{(S)}{[S]}$  upon the final sulphur in the steel for a given sulphur burden on a furnace of 168,000 lb steel capacity.

If the case is considered of 100 lb total sulphur burden on Fig. 16b with  $6 \frac{(S)}{[S]}$ , the relative slag weights for 0.022 and 0.027 pct sulphur steel are 46,000 and 34,000 lb. This represents a tolerance of 12,000 lb in the tapping slag weight.

Alternatively, if a slag weight of 42,000 lb is

Fig. 14—Furnace calculation wheel for lime to feed for 0.035 pct S steel.

Fig. 15—Calculation wheel for lime to feed for 0.025, 0.030, and 0.035 pct S steel.

taken, the difference between 0.022 and 0.027 pct sulphur steel represents a tolerance from 6.8 to 4.8 in  $\frac{(S)}{[S]}$ . The effect of errors of  $\pm 4500$  lb in the slag weight at junction is shown in Table III.

The degree of accuracy that can be obtained is, however, best judged by actual results, and for this purpose we have extracted the results from our No. 2 shop for a period of two months, of all casts made, excluding the first cast of each week, and this is shown in Table IV.\* The comparison between the sulphur percentage ordered and the pit sulphur percentage actually obtained for the same series of casts is shown in Fig. 17.

It will be noted that there is some discrepancy between the calculated and the actual lime additions in certain cases. Where this occurs, the lime fed is, almost invariably, less than the calculated addition. The calculation for the lime addition is based upon a fixed  $\frac{(S)}{[S]}$  at tapping and a fixed amount of lime eroded from the hearth for any particular carbon at junction. If either of these is higher than normal, the amount of lime that need be fed will be less than the calculated figure.

In actual practice in our shops, the latitude allowed in pit sulphur percentage rules the strictness in the pass sulphur percentage before tapping. For instance, when making 0.025 pct sulphur steel, one shop manager allows a furnace to tap after 0.028 pct has been reached with a lapse of 40 min and no further lime addition, provided that the carbon is down to specification even if all the calculated lime has not been added. The manager of another shop feeds all the calculated lime and does no pass tests.

Things will of course tighten up, when the cost office discovers that a 0.020 pct sulphur steel costs more to make than a 0.025 pct steel. The official complaint will then be that the steel is too good for the job and not that it is not good enough.

#### Cost of Making Low Sulphur Steel

The relative slag weights required for making 0.025 pct sulphur steel in a furnace tapping 168,000 lb steel at 6  $\frac{(S)}{[S]}$  are shown by reference to Fig. 11b to be as given in Table V.

Reckoning from yearly consumption of lime and dolomite, the slag weight works out at 20 pct of our ingot production for all grades and over two shops. Steel is manufactured from 0.025 to 0.040 pct sulphur according to the order book. The difference in melting cost (i.e. fuel, reduction in steel, output and furnace repairs) in cash, is not known between our 20 pct slag and the common practice abroad of 8 pct. But on materials alone, the cost of the additional

Fig. 17—Summary of results from two months sulphur control, No. 2 shop. Tapping 168,000 lb. Total of 498 casts. The number of casts is averaged under each point.

\* See footnote on p. 1038.

| 18,800                      | 0.36               | 66            | 0.04                | 66             | 132        | 35,000        | 20.8         | 0.035               |
| 18,800 + 4500               | 0.36               | 84            | 0.04                | 66             | 150        | 39,500        | 23.5         | 0.037               |
| 18,800 - 4500               | 0.36               | 51            | 0.04                | 66             | 117        | 30,500        | 18.1         | 0.034               |

lime and iron oxide (which is derived from the metallic iron of the charge) amounts to 8/6 or \$1.30 per ton of steel.

The shop man using high sulphur raw materials and high sulphur fuel has to consider whether the yet unknown melting cost of at least 12 pct or 19,500 lb of slag per cast, added to 8/6 (\$1.30) per ton for material cost, would not justify the spending of a good deal of money to reduce the weight of sulphur in steel and slag at tapping.

### Sources of Sulphur in Steel and Slag

In our cold metal practice, the sources of sulphur weight in the furnace at tapping are as shown in Table VI.

The ways to reduce the weight of sulphur brought in by the pig iron, scrap, lime, spar and dolomite

Table V. Relative Slag Weights for Making 0.025 Pct Sulphur Steel

| Wt S in Steel + Slag at Tapping, Lb | Slag Wt, Lb | Pct Slag Wt of Metal Wt |
|-------------------------------------|-------------|-------------------------|
| 62                                  | 13,500      | 8                       |
| 82                                  | 26,500      | 15                      |
| 93                                  | 33,600      | 20                      |

are so well known technologically that it remains merely a comparison of costs to choose, whether this incoming total sulphur weight is made small, or whether it is left large and desulphurized in the Siemens furnace at the expense of high slag weights.

We are fully aware of the technological ignorance on the one hand, and the possible money saving on the other hand, of reducing the weight of sulphur picked up from, or discharged to, the furnace atmosphere. We can but publish here such data as we have collected, in the hope that it may serve others. Up to the present, we have been quite unable to tie it together into any furnace practice rules.

### Sulphur Pickup from Furnace Atmosphere

The histograms in Figs. 7 and 8, to which reference has already been made, show the spread of sulphur pickup from, or loss to, the furnace atmosphere, that

Table VI. Sources of Sulphur Weight in Furnace at Tapping

|                | Average Weight per Cast, Lb | Sulphur, Pct | Sulphur per Cast, Lb |
|----------------|-----------------------------|--------------|----------------------|
| Pig iron       | 62,800                      | 0.03-0.07    | 19-45                |
| Uprising scrap | 58,200                      | 0.025-0.05   | 15-29                |
| Bought scrap   | 58,200                      | 0.04-0.07    | 23-43                |
| Lime           | 11,250                      | 0.1-0.2      | 11-22                |
| Dolomite       | 6,750                       | 0.1-0.3      | 7-21                 |
| Spar           | 450                         | 0.6-0.8      | 3-4                  |
| Oil            |                             | 2.3-2.6      | -30-+95              |
|                |                             |              | 48-259               |

had been obtained from charges made in the early stages of adoption of our process. Table VII shows the results for all our controlled charges to date.

It will be noted that the pickup, particularly from junction to tapping, has increased markedly from series V. Though other changes have taken place during the period under review, it is very significant that between series IV and V a change was made in our supply of oil. The sulphur content which was 2.4 to 2.5 pct before rose to 2.6 to 2.8 pct after the change. Table VIII shows the partition of sulphur between slag and metal at junction and tapping. It will be noted that there has been a distinct tendency for the  $\frac{(S)}{[S]}$  at tapping to rise in the same way as the pickup of sulphur has risen. Fig.

18 shows the relation between sulphur pickup between junction and tapping and  $\frac{(S)}{[S]}$  at tapping for a number of individual charges. It can be seen that there is a trend for the high figures for sulphur pickup to be associated with high  $\frac{(S)}{[S]}$  at tapping.

It can perhaps be argued that, if the sulphur passes from the furnace atmosphere to the slag, the sulphur in the slag does not necessarily reach equilibrium with sulphur in the metal, whereas, if the sulphur passes from the metal to the slag, then equilibrium is reached. If there is any truth in this

Table VIII. Partition of Sulphur between Slag and Metal

| Series | Junction |         | Tapping |          |
|--------|----------|---------|---------|----------|
|        | Average  | Range   | Average | Range    |
| I      | 5.8      | 2.3-9.8 | 5.2     | 3.9-8.1  |

Fig. 18—Relation between sulphur pickup, junction to tap and  $\frac{(S)}{[S]}$  at tapping.

explanation, it would help to explain some of the anomalies found between  $\frac{(S)}{[S]}$  by analysis and by excess base calculations in the high  $\frac{(S)}{[S]}$  range.

It is often stated that reducing conditions tend to favor sulphur pickup, so sulphur pickup has been

Table IX. Influence of Weight of Lime Charged on Sulphur Pickup

| No. of Charges | Wt Lime Charged, Lb | Average Sulphur Pickup   |                 |                     |
|----------------|---------------------|--------------------------|-----------------|---------------------|

#### WASTE GAS ANALYSIS SAMPLING LAYOUT

Fig. 19—Layout for continuous waste gas sampling.

plotted against factors likely to influence combustion conditions such as oil flow, steam flow, metered air, percent oxygen in the waste gas, etc., but so far no significant trends have been found. The amount of sulphur pickup from start charge to junction, does however, appear to be influenced by the weight of lime charged. Figures from one series of charges, in which a comparison was made between high and low phosphorus iron, with corresponding high and low weights of lime charged are given in Table IX. The reduced pickup is probably due to rather earlier slag formation and to the reduced amount of lime exposed directly to the flame.

#### Fuel Burning to Control Gas Composition

We have read much and done much work on the furnace control necessary to burn fuel so that the gases sweeping the slag or particular geographic areas of the slag have a particular composition. It seems to us that, much as we want scientists to discover the chemistry of the passage of sulphur between specific mixtures of gases on the one hand, and solid pig, and scrap, solid lime, liquid slags, and liquid steel on the other hand, such knowledge will be of little use, until furnace men can reproduce in the furnace what the scientist may find he wants. Our part of the work may take as long and seem more impossible than theirs, but we think that furnace combustion control must precede any real effort the scientist may make. The stimulus to the scientist will become very real when he knows that we have the tools waiting to apply his discoveries. A start has been made on automatic continuous waste gas analyses and on the control of oil-air ratio on the results.

This problem was divided into two parts: 1—sampling, and 2—the invention of recording automatic analyzer. Sampling is considered to be a furnace fitter's problem and therefore we undertook it ourselves. The instruments were handed over to instrument makers and they were given, at the fur-

Fig. 20—Slag weights required for varying pounds of sulphur in furnaces of different sizes.

nace, a cool clean place and a pipe through which the gas that was to be analyzed passed at a rapid rate to waste.

The sampling arrangements have been successful for  $\text{CO}_2$ ,  $\text{CO}$ , and  $\text{O}_2$ , for which one sampling tube was used. This is shown in Fig. 19 with the testing apparatus both for the gas tightness of the sampling tube and the testing of the correctness of the gas analysis. These analyses are used on the experimental furnace to control the air screw by human link, but it is hoped that this will be incorporated in the fully automatic furnaces now being built.

A steam-lagged sampling tube for water in gas analysis was built successfully, but the instrument makers have, so far, failed in measuring automatically the water condensed in unit time. A satisfactory sampling method for  $\text{SO}_2$  has not been devised and in addition, we are rather doubtful of any recording automatic analysis for  $\text{SO}_2$ , to operate on an open hearth furnace that has yet come to our notice. The difficulty in sampling is that iron oxide is such a good catalyst for  $\text{SO}_2$ - $\text{O}_2$  reaction and that water is such an excellent absorber of  $\text{SO}_3$ . We feel that some day we will have to return to it.

We are very much aware that the waste gases sampled in the downtake at stage level are not representative of the gases sweeping in the hearth at the middle door and much less at the first door. These are the places that count, and we are at a complete loss for the moment as to how to tackle the practical side of any solution that chemists may put forward. We must remember that it is not the chemists' job to give a practical solution. His job is to tell us the chemistry and it is ours to find the practical solution.

### Conclusion

The process, which has been described, has provided us with a simple calculation that enables us to make steel to the sulphur specification required, from available raw materials. The process has been worked out specifically to meet our particular conditions. We would, however like to suggest that it forms a logical approach to the study of sulphur in the open hearth furnace. There should be no reason why it could not be modified to suit other conditions, in cases where sulphur governs the slag bulk.

The fundamental principle that we wish to stress is consideration of weights of slag, and steel, and of sulphur in each, in addition to the percentages of sulphur in slag and steel. The tacit assumption of so many workers, that the slag weight remains constant, is one that we cannot accept, and we should like to urge other investigators not to omit taking the weights into consideration. Fig. 20 gives the relation between pounds of sulphur in steel + slag and slag weight percentage required, assuming an

$\frac{(S)}{[S]}$  of 6 for different sized furnaces.

### Acknowledgments

This paper is presented as the work of John Summers & Sons. Means had to be found to continue to make low sulphur steel on all furnaces, despite increasing sulphur burden. All departments and organizations threw in their weight to achieve this end. The authors were given the job of organizing the work and are only mentioned as three of the gang at whom the technological public might aim their criticisms. Internal acknowledgments are therefore out of place.

We would wish, however, to thank Sir Charles Goodeve, Director of The British Iron and Steel Research Association (and our other friends in The British Steel Industry) for having allowed members of their staffs to give us so much help. They helped us with statistical work and hours of seemingly unprofitable conference, until one day, we found what we have published just lying on our office table.

Finally one of the authors was given much help by a short conversation with John Chipman and C. H. Herty, Jr. at a scientific conference in England.

### DISCUSSION, H. L. Tear presiding

**S. L. Case** (*Battelle Memorial Institute, Columbus, Ohio*)—What effect does the control of slag weight have on the production? If there is high sulphur in the charge at the start, there will be a high slag weight in order to meet the low sulphur specifications. What effect will this have on production?

**C. H. Bacon** (authors' reply)—That is rather a difficult question to answer satisfactorily. Production rate has gone up since we introduced the process, and it enables us to make the required lime additions early. We carried out a trial to compare the use of American low sulphur and phosphorus pig iron with our normal supply and we were able to show a reduction in slag weight and an appreciable increase in production rate. I think I can say we could work faster if we could keep the slag weight lower.

**H. L. Tear** (*Jones & Laughlin Steel Corp., Pittsburgh*)—Our answer to that, Mr. Case, is much different than Mr. Bacon's. It has a great deal of influence on production rates. Fig. 21 shows the lime consumption with the different specifications of sulphur; 80 pct of the heats are in the 0.025 S range and the effect of lower sulphur on lime consumption can be seen. Fig. 22 shows that, with different preliminary sulphur ranges, taking 0.04 as the base, as the first sulphur test goes up there is a loss in production rate, as indicated. With a preliminary sulphur of 0.071 or over, the production rate loss is in the neighborhood of 8 pct, which is much different from that reported by Mr. Bacon.

**Mr. Bacon**—I should just explain, Mr. Tear, that we have never had an opportunity to work with such low slag weights as you carry over here.

**C. R. Funk** (*American Locomotive Co., Latrobe, Pa.*)—Will you give us something on the rates?

**Mr. Bacon**—We have a small furnace and our rate of work is approximately 7.3 tons per hr, or 55 lb per sq ft of hearth area.

**Mr. Tear**—How many pounds of fluorspar?

**Mr. Bacon**—We use an average of 2 or 3 cwt of spar with the charge of 84 tons.

Fig. 21—Sulphur specification vs. lime consumption.

Fig. 22—Preliminary sulphur vs. production loss.

**Mr. Tear**—You add roughly 330 lb of spar per ton?

**Mr. Bacon**—No, per charge, about 3 lb per ton.

**Mr. Tear**—In our case it is around 14 lb of spar per ton of ingots with a slag rate of about 300 lb per ton.

**W. A. Peters** (*Laclede Steel Co., Alton, Ill.*)—How do you get the higher S over S value. If you want it up higher what do you do about getting it up there?

**Mr. Bacon**—The higher S over S values that we showed toward the end were our later charges and we assumed it to be due to the fact that we had a higher proportion of sulphur in the furnace atmosphere and a higher pickup of sulphur to the slag from the furnace atmosphere.

**L. S. Darken** (*U. S. Steel Co., Kearny, N. J.*)—If the sulphur burden is high at junction so that greater lime addition is required, it seems that this would increase the sulphur distribution ratio. The extra time as well as the lime might be expected to increase the sulphur pickup. Thus the correlation between distribution ratio and pickup may be indirect.

**Mr. Bacon**—I do not think we have any figures to show that the sulphur pickup is greater, when more lime is fed.

**C. E. Sims** (*Battelle Memorial Institute, Columbus, Ohio*)—Would the fact that the S over S ratio does increase with sulphur pickup indicate you probably did not have equilibrium between metal and slag? You have mentioned that you thought you did have equilibrium. This might indicate you did not.

**Mr. Bacon**—The suggestion is, that, if the sulphur is coming into the slag from the furnace atmosphere, we probably do not reach equilibrium between slag and metal, but if it is coming from the metal into the slag we are more likely to reach equilibrium.

**W. T. Sergy** (*Jones & Laughlin Steel Corp., Pittsburgh*)—This junction seems to be in every correlation that you make and if I understand correctly a definite bath temperature is desirable at a certain carbon. Do you have any limits or range for bath temperature, or do you aim at one particular temperature for a certain carbon content of the bath?

**Mr. Bacon**—We aim at 0.3 to 0.5 pct C at junction. If we melt out at 0.9 pct C, we want a temperature of 1510°C; at 0.4 pct C, 1560°C.

**Mr. Sergy**—Does every heat have a junction?

**Mr. Bacon**—Yes.

**Mr. Sergy**—Suppose at 38 or 40 pct C you do not have the proper temperature?

**Mr. Bacon**—We do not call that junction from the point of view of taking samples.

**Mr. Sergy**—Do you add lime or any other flux on such a basis?

**Mr. Bacon**—No, we wait until we pick up the temperature and then we take the junction.

**Mr. Sergy**—And if you never get it?

**Mr. Bacon**—We have to pick up the temperature to attain a minimum temperature at tapping.

**Mr. Sergy**—What I am trying to resolve is, do you make any calculations on the amount of lime you would add when you do not have a junction?

**Mr. Tear**—I think Mr. Sergy means, if you get to the point where you have to refigure a heat do you apply this practice to that heat in the case of a soft melt?

**Mr. Bacon**—In the case of a very soft melt, we cannot always add enough lime to reach specification.

**Mr. Sergy**—When junction is not obtained due to too high a bath temperature, do you still make your calculations on that basis?

**Mr. Bacon**—If the temperature is high at the junction we can feed rapidly.

**Mr. Sergy**—And if you are low, you do not?

**Mr. Bacon**—If we melt very soft, we do have to anticipate the junction.

**W. O. Philbrook** (*Carnegie Institute of Technology, Pittsburgh*)—Have you had time to apply the waste gas analysis, and if so has any trend of variation of the sulphur pickup with the oxidizing potential of the atmosphere been noted?

**Mr. Bacon**—We have tried to obtain a relation but have failed so far. We have been using an absorption type of analyzer, which is not altogether satisfactory as it involves a delay of about 4 min. We have now installed a paramagnetic type of meter with a quick response. We shall check this on future charges.

**T. S. Washburn** (*Inland Steel Co., Chicago, Ill.*)—It would be interesting to know whether these relations vary with the carbon content of the bath: for example, 0.60 pct C as compared with 0.10 pct C.

**Mr. Bacon**—The data are all from low carbon steel.

**Mr. Washburn**—Consequently, the relations would not be the same for medium or high carbon.

**R. L. Long** (*Carnegie Institute of Technology, Pittsburgh*, and also from an English steel firm, *The Park Gate Iron & Steel Co., Ltd., Rotherham, England*)—There are two questions I wish to ask. First of all, is your sulphur determination equally rapid, and what is its accuracy? Second, you have mentioned a temperature carbon line for your junction. Is that based on a given superheat, say according to the carbon, or is it based on your own experience as to the suitable stage at which to commence feeding the charge?

**Mr. Bacon**—As regards the accuracy of the rapid sulphur determination in slag at junction, we consider it to be of the order of 5 or possibly 10 pct. On a slag of 0.22 pct S, the rapid method should give a figure between 0.21 and 0.23.

**Mr. Tear**—How did you arrive at the origin of the carbon temperature line?

**Mr. Bacon**—That was arrived at by experience on the furnace.

**Mr. Funk**—What is the depth of the bath? What do you do when you have a furnace that does not work very well? Is there a difference between a sharp working furnace and a sluggish working furnace?

**Mr. Bacon**—The depth of the bath is about 2 ft 6 in. for an 80 ton furnace. A sluggish furnace tends to pick up more sulphur than a sharp working one, but the greater part of this occurs before junction, so the analysis at junction should take care of that.

## Sintering Practice at Josephtown Smelter

by H. K. Najarian, Karl F. Peterson, and Robert E. Lund

DISCUSSION, T. H. Weldon presiding

**R. E. Powers** (Mellon Institute of Industrial Research, University of Pittsburgh, Pittsburgh)—Several of the processing methods at the Josephtown smelter might well be considered by plants producing iron blast furnace sinter. In making blast furnace sinter the objectives are much the same as at Josephtown: To produce a strong yet porous agglomerate which has a size consist in a preferred range. The emphasis however is on production rate rather than on the size or other quality characteristics of the sinter. Therefore the technique is entirely different. Blast furnace sinter plants attempt to make their product in one pass with a minimum recirculating load and without sizing treatment after the sinter leaves the machines. Many plants are beginning to feel that more attention paid to quality characteristics would make the product a more desirable blast furnace material.

The pelletizing of very fine material before placing it on the bed is not deliberately done at iron sinter plants, although the installed equipment sometimes gives a similar action. Such pelletizing seems to be a promising way of accommodating the down-draft sintering process to very fine materials.

The recirculating load at Josephtown is extremely high. Two plants<sup>1</sup> producing blast furnace sinter from raw material of comparable size have a recirculating load of about 100 pct of production. At Josephtown it is notable that the size and the rate of feeding of return fines are under control. This is not the case in most blast furnace sinter plants. The sinter slicer appears to be a worthwhile aid in effecting such control. It is similar in action to rakes and plows used at a number of plants, but it has the advantage that the sinter dislodged is positively removed and not left to the inefficient action of a stationary grizzly screen.

Blast furnace size specifications for sinter are not at present so rigid as the Josephtown specifications. If the sizing of blast furnace sinter does become important, then the Josephtown crushing practice, in which a large recirculating load is maintained on the crusher in order that minimum fines be produced, may be of interest.

Fig. 2—Feed to Dwight and Lloyd sinter machine, Josephtown Smelter.

**H. K. Najarian** (authors' reply)—We note that Mr. Powers appreciates some points that we tried to emphasize in our paper as being of importance in making zinc sinter of good quality and which may well be applied to iron blast furnace sinter.

Fig. 2 shows the pelletized nature of the feed going on to a Dwight-Lloyd type sintering machine in our plant. Practically, the entire feed consists of more or less rounded particles which permit more uniform air passage through the charge, while the larger particles in the charge roll on to the surface of the grate, which helps to keep the grate openings from being clogged by excessive fines. An agglomerated charge of this character may preferably be made by rolling action while being mixed in a rotating drum and wetted by water sprays to bind the fine particles together and give the charge the desired moisture content. From our observations of several iron ore and blast furnace flue dust sintering operations, we believe that if the fines from the sinter discharged from the machines were to be recirculated and agglomerated with the new feed, not only sinter of better quality but larger capacity from the machines may be realized.

# Arc Melting of Titanium Metal

by S. F. Radtke, R. M. Sriver, and J. A. Snyder

## DISCUSSION, J. R. Long presiding

**R. I. Jaffee** (*Battelle Memorial Institute, Columbus, Ohio*)—The authors have written a fine and important paper, and are to be congratulated. I do not entirely follow their discussion of the relationship between the ductility of titanium and its crystal structure. Since high purity titanium is extremely ductile, being capable of cold reductions of over 99 pct, its ductility cannot be unduly restricted by its hexagonal crystal structure. It is true that interstitial solid solutions of nitrogen and oxygen do have a restricting effect on ductility, but this would appear to be an alloying effect rather than a crystal structure effect. The point made by the authors concerning the relative ductility between forged and rolled titanium does not appear to be conclusive, either. It would appear that in the same condition forged material would have equivalent or better ductility than sheet material. The difference between the ductility reported for forged bar and annealed sheet in Table I may be the result of a greater degree of cold work in the as-forged condition.

**S. F. Radtke, R. M. Sriver, and J. A. Snyder** (authors' reply)—We appreciate the discussion by Dr. Jaffee. His point is well taken that the hexagonal structure of titanium does not, in itself, restrict the ductility of iodide material and, therefore, should not be limiting in this case. It is true, however, that the ductility of different grades of titanium is not necessarily related to their hexagonal structure but more likely to their orientation and composition. It is also true that the presence of small amounts of foreign elements in hexagonal metals may have more pronounced influence on ductility than a corresponding quantity in cubic metals.

Average values from a large number of tests might show relatively better ductility for forged titanium than is recorded in Table I. The forged bars used in this work were tested in the annealed condition; little is known concerning the effect of forging practice on ductility in titanium metal.

## Thermodynamics of Iron-Silicate Slags: Slags Saturated with Gamma Iron

by R. Schuhmann, Jr. and P. J. Ensio

### DISCUSSION, N. Arbiter presiding

**John Chipman** (*Massachusetts Institute of Technology, Cambridge, Mass.*)—The activity of FeO in silica-saturated slags shown in Table V is about 0.40 in the temperature range 1260° to 1350°C. Recent

measurements by N. A. Gokcen at 1600° lead to about the same value. He finds the oxygen content of liquid iron in equilibrium with silica and ferrous silicate slags to be 0.088 pct. Under pure iron oxide slags at the same temperature, it is 0.225 pct. The ratio places the activity at 0.39.

## Metallurgical Reactions of Fluorides

by Herbert H. Kellogg

**C. M. Decroly** (*University of Brussels, Belgium*)—The importance of the fluorides in the process metallurgy of special metals has already been accepted and it will probably increase in the future. Free energy diagrams as such established by Professor Kellogg are therefore very useful.

It is interesting to note that the absolute value of the standard free energy of formation of HF increases with temperature, whereas for almost all the other fluorides it decreases; consequently it should be theoretically possible to reduce all the fluorides of the metals which, at low temperature, have a greater affinity for fluorine than hydrogen by this last element, provided a sufficiently high temperature is used in order to have a good efficiency.

However, with regard to the reduction of UF<sub>6</sub> by hydrogen, I doubt that it will be possible to obtain directly the metal at comparatively low temperatures. There are other uranium fluorides which are more stable than UF<sub>6</sub> and it is very likely that such fluorides will be obtained first. For example, in considering the reaction:

it is found, using the thermodynamic data of Brewer et al, that  $\Delta H_{298} = -66$  kcal and  $\Delta G_{298}^{\circ} = -65.2$  kcal.

As a result, the reduction of UF<sub>6</sub> to UF<sub>4solid</sub> should proceed spontaneously even at ordinary temperature. On the other hand, the standard free energy of formation of UF<sub>4solid</sub> at 298°K is  $\Delta G_{298}^{\circ} = -209$  kcal per mol of F<sub>2</sub>. The reduction of UF<sub>4</sub> by hydrogen will be practically difficult and, as it is known, the only practical way of reducing this compound is to use alkaline-earth metals such as calcium or magnesium. I should like to point out, further, that the fluorination of many metal oxides can be carried out very easily by using the ammonium difluoride method of preparation, which renders the use of fluoride gas unnecessary. The first compound formed is generally a double fluoride of the metal and ammonium. This compound can be decomposed by heating either in a vacuum or in an inert atmosphere, ammonium fluoride being volatilized leaving the metal fluoride in a very pure state.

**H. H. Kellogg** (author's reply)—Professor Decroly is quite right in pointing out that the formation of lower halides of uranium may complicate the reduction of UF<sub>6</sub> by H<sub>2</sub>. I was unable to find his reference to the free energy of formation of UF<sub>4</sub> in the compilation of Brewer,<sup>13</sup> however. The value of  $\Delta G_{298}^{\circ} = -209$  kcal for formation of ½ UF<sub>4</sub> seems rather high, and I hope the source of this value may be made clear.

## Thermodynamic Study of the Reaction $\text{CaS} + \text{H}_2\text{O} \rightleftharpoons \text{CaO} + \text{H}_2\text{S}$ and the Desulphurization of Liquid Metals with Lime

by Terkel Rosenqvist

DISCUSSION, W. O. Philbrook presiding

**J. Chipman** (Massachusetts Institute of Technology, Cambridge, Mass.)—The fact that the experimental work has been applied to copper rather than iron and that the paper is presented to the Iron and Steel Division, I regard as rather significant. It shows the unity of metallurgy and the fallacy of trying to cut it up by metals. This result for the solubility of sulphur in molten copper correlates with Professor Schuhmann's finding that the published data on the other side of the copper-sulphur miscibility gap are also in error. I should like to ask the author to say a little bit more about the sulphur capacity of the slag.

**T. Rosenqvist** (author's reply)—I hope that Dr. Chipman will find the derivation of the expression for sulphur capacity more clearly explained in the printed version of the paper than in the oral discussion at the meeting. I feel that this quantity, which actually is the ratio of two activities, can be measured more easily than the individual activities. Even if the ratio  $\text{CaO}/\text{CaS}$  is chosen as the standard state, the expression can be used for any slag, even for slags completely free of lime, and it represents a way to put the desulphurizing power of all slag constituents into one bag.

Some doubt has been expressed as to whether oxygen ions really exist in calcium oxide and in molten slags. From a thermodynamic view point that question is of minor importance. The term oxygen ion activity, or any activity for that matter, is defined rigorously by the equation:  $\text{activity} = \exp \mu/RT$ , where  $\mu$  is the change in free energy connected with the transfer of one mol of ions from the standard state into the slag. Whatever happens to the ion in the slag is of no concern to the thermodynamicist. Regardless of whether the ion is "free" in the slag or not, or whether it is present in a very small amount, its activity can always be expressed, and for a thermo-

dynamic calculation that is all we need. However, ionic activities will only be of some real value if they are simple functions of the slag composition, or can be measured easily.

Concerning the real nature of the oxygen in the slag, my feeling is that the oxygen atom has a rather multiplex nature depending on how strongly it is tied by covalent forces or polarized by the other atoms or ions present. The oxides of iron, cobalt, and nickel differ from calcium oxide and blast furnace slags as to the amount of free electrons that can give rise to electronic conductivity. In slags we know that the conductivity is mostly ionic. The fact that reversible emf's can be obtained with oxygen electrodes in certain salt melts, indicates a significant amount of oxygen ions in these melts. But extended work, e.g. polarographic studies and measurements of transference number, are needed to obtain quantitative information about the real structure of the slags.

**D. E. Babcock** (Republic Steel Corp., Youngstown, Ohio)—With reference to the ion, it might be well to remember Dr. Moses Gomborg. All of his life he had no use for the ionization theory and he contributed greatly to the field of chemistry on the assumption there was no such thing as ions. I do not think we have to worry about whether the oxygen is ionic or not. I think one thing specifically should be brought to your attention and this I think is one of the important contributions of Dr. Rosenqvist. He pointed out what we know as oxygen potentials or what is described as oxygen potentials. I have used this concept for a long period of time and I want to state that if this concept is properly applied, it vitiates much of what we have in the literature, or makes our usual ideas regarding oxidation seem primitive. That one thing is more valuable than almost all the rest of the discussion as a fundamental basis on which to build a reasonable in-

Fig. 9 (above) — Apparatus used in studying the reaction between calcium oxide and hydrogen sulphide.

Fig. 10 (left) — Apparatus used to prepare hydrogen and hydrogen sulphide mixed gas.

Fig. 11 — Effect of temperature on the equilibrium constant.

terpretation of some of the oxidation phenomena which up to date are poorly interpreted.

It is interesting to bring up another point that Dr. Rosenqvist mentioned about the hydrogen sulphide-water equilibrium, etc. He mentioned the blast furnace in passing. The data of Dr. Darken and some

others indicated that as the moisture went up in the blast furnace, sulphurization was somewhat better. I have been told it is a statistical phenomenon, but it stirs up one's curiosity to do a little looking around relative to the reason that this fact has existed. We do not have anything like the whole answer to this.

If you use the concept of the saturation point of slag and compute the kinetics in the blast furnace, you find if the blast furnace is operated like the laboratory experimental runs, it would not produce. It is interesting and there is more to look at than appears on the face of the data. We have looked so long at the slag, many of us are blinded by the fact that from 75 to 90 pct of all the desulphurization occurs before metal is in contact with a liquid slag.

**Tatsuji Uno** (*Hokkaido University, Sapporo, Japan*) — I have been studying the desulphurization reactions of iron and steel for many years, and finished the study on  $\text{CaO} + \text{H}_2\text{S} \rightleftharpoons \text{CaS} + \text{H}_2\text{O}$  several years ago, but had not been able to publish it, because of the difficulty of printing during and after the war. Fortunately, I could publish it in the *Journal of Iron and Steel Institute of Japan* (*Tetsu to Hagane*), January 1951.

The apparatus used is shown in Fig. 9. Passing the mixture of  $\text{H}_2\text{S}$  and  $\text{H}_2$  over  $\text{CaO}$  and regarding the difference of  $\text{H}_2\text{S}$  content in the gas mixture before and after the reaction as  $\text{H}_2\text{O}$  formed, the equilibrium constant for this reaction was calculated as  $K = p_{\text{H}_2\text{O}}/p_{\text{H}_2\text{S}}$ .

When  $\text{H}_2$  gas passes through  $\text{H}_2\text{S}$  producer shown in Fig. 10, a mixture of  $\text{H}_2\text{S}$  and  $\text{H}_2$  of desired composition is obtained by heating  $\text{Bi}_2\text{S}_3$  at the proper temperature. Therefore, it can be said that my experiment was carried out from the opposite side compared to Dr. Rosenqvist's. I obtained following results from 1000°C to 1100°C:

$$\log K = 3231.8/T - 0.060 \text{ (Fig. 11)}$$

As I used transparent quartz tube, it was difficult to make determinations above 1100°C, and the amount of  $\text{H}_2\text{S}$  at 900°C, was so small, that the experimental errors had largely affected the results. For these reasons, my experiment was limited to a small temperature range.

But I am much pleased to find that your results, obtained over a wide temperature range, are in good agreement with mine.

**Dr. Rosenqvist**—It is a great pleasure to see that Dr. Uno, with a different technique, has arrived at equilibrium values very close to those obtained in my investigation. In the temperature range 1000° to 1100°C the two sets of values differ by 100 cal or less, which is as good as one can expect in work of this kind. The fact that Dr. Uno has approached the equilibrium from the opposite side as compared to my work, shows that true equilibrium has been obtained.

It is only regrettable that the publication of Dr. Uno's work has been delayed so his data were not earlier brought to my attention.

## Effects of Manganese and Its Oxide on Desulphurization by Blast-Furnace Type Slags

by Nicholas J. Grant, Ulf Kalling, and John Chipman

### DISCUSSION, D. C. Hilty presiding

**D. E. Babcock** (*Republic Steel Corp., Youngstown, Ohio*)—I would like to know what evidence you have to prove the  $\text{MnO}$  was pure  $\text{MnO}$ . I would also like to know whether you might not explain it on the basis of a temperature reversion; and, was it due to the oxidizing power of  $\text{MnO}$ ?

**N. J. Grant** (authors' reply)—Briefly, we have no proof that pure  $\text{MnO}$  was used. The manganese oxide was added as chemically pure  $\text{MnO}_2$ .  $\text{MnO}$  is assumed as the oxide in the reacted slag following standard

molecular slag theories, especially under the reducing conditions of these experiments. The noted sulphur reversion cannot by any means be explained on the basis of a temperature reversion since the temperature effect is shown in this paper to be very small. Until a more logical explanation can be offered, backed I hope by some experimental proof, we propose to explain this sulphur reversion as stated in the paper, namely, that it is due to the oxidizing effect of the added manganese oxide.

**Member**—How did the oxygen in the slag give you a reversion of sulphur? What was the mechanism there?

**Dr. Grant**—One of the simpler possible explanations is that the oxygen replaces the sulphur in calcium sulphide, for example. The reaction might be written as follows:

**Dr. Babcock**—This paper was entitled in relation to blast furnaces. The inference was made that it is a laboratory analogy of a blast furnace process.

**Dr. Grant**—That is exactly what was intended.

**Dr. Babcock**—I think that is not a good idea because it gives us a notion that some things happen in a blast furnace that just do not happen. For example, we get results in a blast furnace that do not fit this picture. You say calcium oxide is several hundred times or so, as effective as MgO. Is that correct?

**Dr. Grant**—That is right.

**Dr. Babcock**—We can, by statistical methods, operate on plant data to determine what the effect is, pretty closely. It is not of that order of magnitude.

The next thing that is of interest is the fact that MgO is in a slag system in which perhaps the physical chemical equilibrium between the associated groups would lead to the conclusion that MgO at any other time could by simple mass effect displace the lime from combination with the other ions or molecules, or whatever you have, so that to discriminate and infer that the effect is only due to lime and not due to lime displacing magnesia in certain systems, I think would be false.

It has been a serious problem to tie together the data of Mr. Hatch, where he figured in his report published by the AIME that the mol for mol excess equivalent effect of magnesia as compared to lime was on the order of two-thirds. Now, we have a ratio of a couple of hundred. The difference of two-thirds effective as lime and a couple of hundred, is a wide gap. Would you put those two things together?

**Dr. Grant**—Such evidence of the superior desulphurizing power of CaO over MgO, notwithstanding manipulated statistical data, is presented in this paper in graphical form, and was also shown for the Hatch and Chipman<sup>8</sup> data in a recent paper by Sherman and Grant.<sup>9</sup> The results from these two different sets of data are in full agreement. The thermodynamic substantiation of the vastly superior desulphurizing power of CaO compared to MgO is noted in the 1600°C equilibrium constants recently calculated by Chipman (*Basic Open Hearth Steelmaking*, Chap. XVI, 2nd Edition, 1951, AIME), and reported in the work of Rocca, Grant and Chipman.<sup>8</sup>

**B. M. Larsen** (*U. S. Steel Co., Kearny, N. J.*)—On the practical effect of MgO on sulphur we propounded some data and Kennedy did some work after that, and we found other data later on. All seem to agree that up to around 6 or 8 pct MgO in the slag, the sulphur ratio increased and above that it seemed to fall off again. From that we inferred that the probable effect of MgO was mainly to give more fluidity to the slag and perhaps thus increase the reaction rate.

**Dr. Grant**—I think that in the case of actual blast furnace work, where the fluidity of the slag and the degree of mixing can be extremely important, that you can ascribe it to the effect of fluidification through the addition of MgO; but if MgO is a good desulphurizer,

why should the sulphur ratio fall off after 6 or 8 pct MgO?

**Member**—The answer to the MgO is that by putting more into the basic slag you get into trouble with the basic slag itself.

**Mr. Larsen**—There is very likely a wider range of fluid slag compositions with more MgO. But the only point is in respect to the assumption involved here. We do not really know what the liquid constitution of the slag is, and I think maybe the authors might be willing to admit these are rather wild approximations.

**Dr. Grant**—They may not be exact, but they are hardly wild.

**C. L. T. Edwards** (*Dept. of Commerce, Washington, D. C. Temporarily with the Industrial Evaluation Board*)—I like everything the speakers have had to say thus far and was particularly impressed with the slight reversion as indicated in the curve.

The heat of combination between magnesium and sulphur is 2481 cal per unit weight of sulphur; the heat of combination between calcium and sulphur is 2947 cal, showing very definitely that calcium, theoretically, has a higher affinity for sulphur than magnesium does and I have found in practice, it has worked out that way in the blast furnace.

Now, in connection with manganese, iron and sulphur, I would like to tell you how, in my very small way, a few simple experiments were made in order to obtain some visible evidence concerning reactions. You scientists might do this on a more thorough scale and come up with something that is really good. Many of you, undoubtedly, have heated a mixture of powdered iron and powdered sulphur. If any of you have not done so, or seen it happen, touch the side of the crucible with a Bunsen flame and as soon as the reaction begins, remove the flame and you will find the heat will progress uniformly across the body of the mixture and, without benefit of a pyrometer, I would say the temperature of the reaction would be somewhere around 1700°F.

The heat of combination between manganese and sulphur is almost exactly double the heat of combination of iron with sulphur. Make up a mixture of manganese and sulphur in atomic proportion. Be very very careful, because the resulting reaction will be dangerous. Move the flame to the side of the crucible and be sure to have a shield for protection, as the reaction is most violent and you are lucky if everything does not fly out of the crucible. What the temperature will be, I do not know, but would guess it to be somewhere around 2700° or 2800°F.

Now, here is where the pay-off comes. Take iron sulphide, FeS, and mix it with powdered manganese; move the flame to the side of the crucible and you will find a reaction that takes place at somewhere around 1700°F. The indications are, of course, that manganese is about twice as potent a desulphurizer as iron, and it might be a good idea to keep that in mind and think about it.

I believe it to be a worthy assumption, that, since manganese sulphide has such a high melting point, there is a strong tendency for it to coagulate in the molten metal and the problem at once becomes one of mechanics, i.e., how to bring these coagulations into contact with the slag under a nonoxidizing, or reducing, atmosphere. Do not make the error of writing off manganese—learn how to use it.

## Effect of Silica Reduction on the Desulphurizing Power of Blast-Furnace Type Slags

by Nicholas J. Grant, Olaf Troili, and John Chipman

DISCUSSION, D. C. Hilty presiding

**D. C. Hilty** (*Union Carbide & Carbon Research Laboratories, Niagara Falls, N. Y.*)—How does this effect of silica compare with the effect of silica in combining with the lime in the slag to reduce the activity of CaO, thereby affecting the first equation?

**John Chipman** (authors' reply)—That is the object of showing this effect for slags of two different basicities. In the more basic, the silica is more firmly tied up in the slag and is less easily reduced. It is therefore less able to interfere with desulphurization. The important point is that silica is acting in two ways. Of course it is an acid and as an acid it ties up lime and in tying

up lime it interferes with desulphurization; but it also acts as an oxidizing agent as I have shown, and this interferes in a second way with desulphurization.

Alumina, on the other hand, although it may be an acid, does not prevent rapid desulphurization because the alumina is not reduced to any substantial extent.

In the case of MnO, we have a basic oxide which ought to supplement the other oxides in neutralizing silica or taking sulphur out of the metal, but in spite of that it interferes with desulphurization on account of its strong oxidizing power.

**D. E. Babcock** (*Republic Steel Corp., Youngstown, Ohio*)—On the first equation you have used carbon as a reducing agent and referred to the fact you did not have carbon on the open hearth. Would you not think the iron bath is a pretty powerful reducing agent with a tremendous potential?

**Dr. Chipman**—The reducing potential of the iron bath depends entirely on the oxygen content and other metals present. In the open hearth it is not a powerful reducing agent, especially at low carbon content.

**Dr. Babcock**—It is common practice to use a bessemer converter to blow out the manganese and silica, leaving the carbon almost untouched for quite a long time, indicating the carbon is not available for reaction. That is the same experience we had when we desilicized iron in the open hearth. We take out the manganese and silica, direct proportions one to the other, but do not lose the carbon, meaning the carbon in kinetic reaction is extremely slow to react. Why do we have to use carbon when it could just as well be manganese, which reacts more rapidly, or silica alone, which is more powerful and readily available to react with lime?

**Dr. Chipman**—Not necessarily. We have expressed the equations with carbon as the reducing agent since under our conditions it is the most powerful reducing agent present both in the blast furnace and in most of our experiments. The fact that silicon and manganese are removed by blowing or oreing hot metal has no bearing on the problem. The behavior of these elements is highly dependent on the slag which is entirely different in the two cases.

**Dr. Babcock**—Then are you not making the assumption

that the carbon controls the end limit and does not prescribe the mechanism, because the assumption is based on final equilibria state and not the process in between?

**Dr. Chipman**—Of course, and the equation represents, as I have said, the simplest possible way we can write the desulphurization reaction. If you wish to write it in kinetic steps (and we do not know what the steps are) the result would be most complex.

**C. E. Sims** (*Battelle Memorial Institute, Columbus, Ohio*)—We know we can get substantial desulphurization under oxidizing conditions in either the open hearth or electric furnace. Do you think the first reaction illustrates the basic reaction under this condition?

**Dr. Chipman**—This illustrates the reaction when you have carbon present. If you wish to let the "C" represent dissolved carbon, it still represents the reaction, although at a much lower carbon potential. The whole question of this reaction in intermediate slags of electric furnace type which lie between basic open hearth and blast furnace, is going to be the subject of a paper (Rocca, Grant, and Chipman) and for this reason, I would rather omit the question for the present.

**L. S. Darken** (*U. S. Steel Co., Kearny, N. J.*)—This general picture that a deoxidation, involving the removal of a relatively small amount of oxygen, is the slow step in the overall desulphurizing reaction seems to fit well the data presented. This automatically raises the question as to how we are to interpret the fact that oxygen is such a stumbling block for desulphurization, and I was wondering what Dr. Chipman would think of the possibility of blaming the slowness on the difficulty of gas nucleation?

We might think that oxygen from the MnO or the SiO<sub>2</sub> would be removed by the carbon as carbon monoxide, but if there is no gas phase in immediate contact with metal and slag, then gas bubble nucleation would be required. Does the difficulty of such nucleation fit your general picture as responsible for the slowness?

**Dr. Chipman**—I have no picture that is contrary to that. I think it is as good as any other but I had not hoped at this stage of the study to be able to identify the slow step.

## Distribution of Sulphur Between Liquid Iron and Slags of Low Iron-Oxide Concentrations

by R. Rocca, N. J. Grant, and J. Chipman

DISCUSSION, D. W. Murphy presiding

**D. E. Babcock** (*Republic Steel Corp., Youngstown, Ohio*)—With reference to eqs 7 and 8, at what temperature do they apply?

**John Chipman** (authors' reply)—That was 1600°C.

**Dr. Babcock**—You have  $1 \times 10^{-4}$  as the component for the lime and  $1$  or  $4 \times 10^{-3}$ . Now, is it by dividing one into the other you get the 400? That is assuming equivalent activity on the part of oxygen, sulphur, and magnesia.

**Dr. Chipman**—Yes, they are calculated for 1600. Now, the first one for CaO was calculated before we had a glimpse of Dr. Rosenqvist's paper.<sup>18</sup> If you take his calculation you get 14,000 cal which is very good agreement, but our calculation would be superseded by Dr. Rosenqvist's new data.

**Dr. Babcock**—The state you assume those to be in is the liquid state, as near as you can measure?

**Dr. Chipman**—Naturally it is based on the solid CaS, but if you add the effect of fusion on both sides it just about balances out, so the ratio would be about the same.

**B. M. Larsen** (*U. S. Steel Co., Kearny, N. J.*)—If we knew the activity of sulphur in the slag instead of merely the percentage, we might be able to find some

conflicting factors that balance one another out, and find that the FeO or oxygen pressure effect is really present over the whole range.

**Dr. Chipman**—I am fairly sure we would. The activity of sulphur in the slag and the activity of CaO in the slag, if we just knew those quantities, would enable us to save a lot of this computation and assumption and all the approximations we are doing now.

**Mr. Larsen**—Two other points perhaps should be included: 1—an independent effect of manganese in helping the desulphurization; and 2—the number of mols of constituents or number of mols of ions or whatever there is in the slag could vary with these compositions in such a way that you get dilution effects.

**Dr. Chipman**—You can figure all that in if you want to and it might improve the degree of approximation a little bit. Maybe enough to justify the labor of calculation, maybe not, but we did not do it.

**L. S. Darken** (*U. S. Steel Co., Kearny, N. J.*)—The authors have tackled a very complicated problem in trying to tie together in one picture the desulphurizing problem over the wide range of basicity and oxidation level from that of the open hearth to that of the blast furnace. At the present state of our knowledge of slags such an ambitious undertaking necessarily involves the adoption of numerous hypotheses.

Their formulation (eq 11) for the higher FeO range

<sup>18</sup> T. Rosenqvist: JOURNAL OF METALS (July 1951), Trans. AIME, p. 535. Discussion, this issue, p. 1047.

is similar to that presented by Darken and Larsen<sup>10</sup> except that manganese is absent in the present case. This is based on a molecular picture of slag composition, which seems less valid now but is still used because we have no adequate way of expressing the relation otherwise. The principal difference of the present treatment is the bald assumption that the distribution coefficient ( $L_{FeS}$ ) for iron sulphide varies rather markedly and gives rise to the minimum of the curves of Figs. 6 and 7. The evidence as to the nature of this variation seems rather meager, particularly as  $K'$  is apparently assumed constant;  $K'$  might reasonably be expected to vary as much as  $L_{FeS}$ , or even more, by virtue of the arbitrary nature of the calculated excess CaO. Thus the conclusions as to the effect or lack of effect of FeO (in the higher range) on the desulphurization ratio seem rather questionable. This is emphasized by the fact that the authors reach the conclusion that the sulphur combined with lime becomes negligibly small if FeO exceeds 10 pct. The efficacy of lime as a desulphurizer in this range is well attested by both mill and laboratory experience; the attribution of this effect to secondary factors seems misleading.

Since the melts of this investigation were made in a magnesia lined furnace, the slags were presumably saturated or nearly saturated with magnesia. Hence the activity of MgO is substantially constant and the contribution of MgO to the desulphurizing power of the slag would be difficult if not impossible to detect.

**Dr. Chipman**—Dr. Darken's remarks as usual are quite correct but apply mainly to the oxidizing ranges of the slag. The treatment here does not differ too much from that of Darken and Larsen.<sup>10</sup> We did not have manganese to put into the equation so that simply makes it easier. We did not know how the FeS distribution would vary with composition. We were a little afraid to assume it was constant as had been done before so we just arbitrarily said that we will suppose it is proportional to the FeO content of the slag. Certainly, we have no evidence one way or the other that this has any merit. That turns out to be a small part of the consideration in the more reducing slags with which we have been here primarily concerned. The introduction of the high FeO slag was brought into the paper mainly to show the relationship between the low FeO slags about which the paper was chiefly con-

cerned and the high FeO slags that had been studied previously. The contribution of the paper lies in the field of the low FeO slags and we claim nothing new with respect to the high FeO.

**D. J. Girardi** (*Timken Roller Bearing Co., Canton, Ohio*)—I am left with the impression that for reducing slags where FeO values are somewhere around 4 pct and under, the FeO value is much more important than the lime silica ratio; is that correct?

**Dr. Chipman**—That is correct according to our findings; perhaps not as high as 4 pct, from 2 pct on down, the FeO content is much more important than the lime.

**Dr. Girardi**—It seems as though the lime silica ratio has an insignificant effect.

**Dr. Chipman**—Not insignificant, but a small effect compared to the FeO.

**Mr. Larsen**—You do not see that some of these deviations vary much on a log scale that way. We noticed, for example, that there were large deviations in very basic high MnO slags when we tried to calculate on an excess basis concept. You tend to get ratios up to 13, 14, 15 to 1 (slag sulphur to metal sulphur) yet you cannot very well explain it on a straight excess base.

**Dr. Chipman**—How do you explain it?

**Mr. Larsen**—It fits if you consider the MnO and the free CaO as affecting the sulphur activity independently and additively. Of course, I will admit the old formula of ours was very rough.

**Dr. Chipman**—I think you have something there because MnO in the open hearth is a better desulphurizer than we have given it credit for. We have talked about MnO not being a good desulphurizer in the blast furnace slags because of oxidizing power where you do not want oxygen, but where you are already highly oxidized as in the open hearth slag-metal system, then the MnO no longer has an oxidizing power, it may be at equilibrium with Mn in the bath or substantially so. Eqs 7 and 8 show the values for  $K$  for CaO and MgO. I want to show you how MnO fits into this.

The value of  $K$  for CaO is about 400 times that for MgO. Comparing CaO with MnO the  $K$  is only twice as large. Thus MnO is a much better desulphurizer than MgO and nearly as good as CaO.

**Mr. Larsen**—Practical experience would indicate that the ratio of effect between CaO and MnO is only 2 or 3 or even less.

**Dr. Chipman**—Yes, I think it would.

## Desulphurizing Molten Iron with Calcium Carbide

by S. D. Baumer and P. M. Hulme

DISCUSSION, T. L. Joseph presiding

**B. M. Larsen** (*U. S. Steel Co., Kearny, N. J.*)—Could we have some sort of an estimate on the cost of calcium carbide for this treatment? Also, if you used calcium carbide on carbon-saturated iron, would some effect hold back the reaction?

**P. M. Hulme** (authors' reply)—As far as I know we have not worked on carbon-saturated iron. About 3½ pct C is the highest we have worked on. As far as cost goes, it depends on how much sulphur you have to take out. It will run anywhere from \$0.75 to \$2.00 a ton overall cost including the cost of carbide per ton of metal treated. That is, using the efficiencies that we show in this paper. We are getting better efficiencies now.

**T. L. Joseph** (*University of Minnesota, Minneapolis, Minn.*)—Did you say 2 lb of calcium compound?

**Mr. Hulme**—That is based on 10 lb of calcium carbide per lb of sulphur removed.

**D. E. Babcock** (*Republic Steel Corp., Youngstown, Ohio*)—We have run this type of desulphurization process at the blast furnace. We have desulphurized between 100 and 200 at the blast furnace and taken the

iron right out of the furnace with an injector system. The process gave us quite varied results; stratified iron, high sulphur on the top and low sulphur on the bottom, and we decided it was impractical.

**Mr. Hulme**—Just what was the type of injection equipment?

**Dr. Babcock**—Nitrogen gas for one injection method and we used fairly large gun equipment. We followed the same general type of pattern you show only on a larger scale.

**Mr. Hulme**—It sounds very much like what we call the gale of wind method. We have very erratic results with that.

**Dr. Babcock**—We have tried several types, and particle sizes. The operation was not satisfactory.

**Mr. Hulme**—Of course, we have never tried it on that scale except on a continuous basis. That is the reason we abandoned the idea of working on 35 ton ladles on a batch principle and took it as it came out of the cupola and treated it on the fly on a continuous basis.

**Dr. Babcock**—When you compare the relative effectiveness of the process as carried out, it does not give a very favorable comparison of that process which is already developed. We did not feel it was worth the

money and effort to go any further, since it did not show the performance and simplicity of the other process.

**Mr. Hulme**—I am a little doubtful of its value on the blast furnace scale. It seems to have possibilities in the foundry.

**Dr. Babcock**—That may be true.

**John Chipman** (*Massachusetts Institute of Technology, Cambridge, Mass.*)—There is one question I would like to ask; it has to do with the use of calcium carbide and calcium oxide together in the desulphurization. As I recall, the efficiency of calcium carbide as

a desulphurizer was considerably damaged by the presence of calcium oxide. This suggests the possibility that something is going in with calcium oxide, perhaps calcium carbonate or calcium hydroxide or some other impurity of an oxidizing nature. If that is so, perhaps it should be repeated, using dead burned lime along with the calcium carbide.

**Mr. Hulme**—It was burnt lime and probably had some hydroxide in it.

**Dr. Chipman**—It might be quite different with freshly burned lime then.

**Mr. Hulme**—You are right.

## Desulphurization of Pig Iron with Pulverized Lime

by Bo Kalling, C. Danielsson, and Ottar Dragge

and

## Kalling-Domnarfvet Process at Surahammar Works

by Sven Fornander

### DISCUSSION, T. L. Joseph presiding

**L. F. Reinartz** (*Armco Steel Corp., Middletown, Ohio*)—I would like to know, in the practical application of the Kalling process, what kind of a lining was used, how thick was the lining, and how much metal was treated at one time?

**S. Fornander** (author's reply)—The rotary furnace is lined with a course of fireclay bricks 6 in. thick. This course is backed by 5 in. of insulation. The furnace has a capacity of about 15 tons.

**Mr. Reinartz**—How was the ladle preheated?

**Mr. Fornander**—As pointed out in the paper, the furnace was heated by a gas flame in the beginning of the experiments. During these first tests, however, the desulphurization was inconsistent. We think that this was due to the fact that iron droplets sticking to the furnace walls were oxidized by the gas flame. Now, the furnace is operated without preheating of any kind, and the results are much better.

**T. L. Joseph** (*University of Minnesota, Minneapolis, Minn.*)—I might add one comment. This furnace was heated with a flame and for a time they had a little difficulty due to some residual metal in the rotating drum that would oxidize in between treatments and they found therefore, that it was very essential to drain the drum completely of metal so that they would not build up any ferrous oxide between treatments and they eliminated some of their erratic heats by maintaining those more reducing conditions.

It was interesting to watch this operation. As soon as the drum started to rotate there was considerable flame, at least, at the time I saw it, that came out around the flanges, indicating there was quite a little pressure on the inside of the drum.

**W. O. Philbrook** (*Carnegie Institute of Technology, Pittsburgh*)—Is the reaction slag in the Kalling process liquid or solid, and how is it separated from the metal?

**Mr. Fornander**—In the process there is no slag in the usual sense of the word. The lime powder does not melt during the treatment. After the treatment the lime is still in the form of a fine powder. It is separated from the metal by means of a piece of wood of suitable size placed within the furnace before it is emptied.

**D. C. Hilty** (*Union Carbide & Carbon Research Laboratories, Niagara Falls, N. Y.*)—Dr. Chipman has given us some of his ideas in connection with a specific effect of silicon and silica on sulphur elimination and how silicon might interfere with desulphurization

in the blast furnace. I wonder if he would like to elaborate on the possibility of a similar effect of silicon in the Kalling process?

**J. Chipman** (*Massachusetts Institute of Technology, Cambridge, Mass.*)—Silicon does not interfere with the Kalling process. Anything that has strong reducing action is good for desulphurization. In these tests where the temperature was low compared to blast furnace temperatures, the silicon that is in the metal is a better reducing agent than the carbon. At high temperatures, carbon is the better. It is not the silicon in the metal that interferes with desulphurization, it is the silica in the slag.

**Mr. Joseph**—I might add that the metal that was tapped from the drum after desulphurization was really at quite a low temperature. It was not measured, but I think it was well under 1300°C, probably 1200° or a little above that. That was one of the difficulties, and I think there is no question about the fact that the Kalling process—in that it affects desulphurization between powdered lime, solid and liquid iron—is a reaction definitely between the solid lime and the liquid iron.

**E. Spire** (*Canadian Liquid Air, Montreal, Canada*)—This Kalling process seems very interesting to us and after all it is only a mixing action that is taking place between the iron and the slag. We have attempted to do the same thing in another way. We have placed at the bottom of the ladle a porous plug through which we injected an inert gas. It can be nitrogen or argon. This plug is placed at the bottom of the conventional ladle and gas injected through the plug. That has appeared in our patent.

To define this new type of treatment, I use the word gasometallurgy. I do not know if you like it, but it is a way of defining methods of treating metal using gases. What we do is exactly what is done in the exchange process in another way. We have a porous plug at the bottom with a high lime slag on top of the metal. Using this method, we have very good agitation of metal and slag, and with a small flow of gas, we can achieve a very strong agitation. For instance, in the 500 lb ladle, we use only 5 liters of gas a minute. We have an agitation compared to very rapidly boiling water in a pail. Moreover, the agitation can be controlled to create any amount of mixing desired.

In a few minutes, with this method, the sulphur dropped from 0.58 to 0.11. These results have been improved since, and we have obtained results like 0.08

to 0.015 in a matter of 10 min, but what is interesting is that we have been able to do that in steel, too.

In steel, we have done exactly the same thing with a high lime slag containing a certain amount of carbon. We have obtained a reduction of 0.5 to 0.25 or, recently, from 0.5 to 0.020. This is interesting because it was done in only 3½ min, and these results, I think, are worth-while because it could be very well used with furnaces where no desulphurization can take place.

All of this work has been done with the help of the Canadian Government and the Bureau of Mines, Ottawa, (now, the Department of Mines and Technical Surveys). I just wanted to point out this new process as having good possibilities in the iron and steel industry where the sulphur problem is such a big one.

**Mr. Joseph**—Will you tell us about the gas that goes in and the slag that is formed?

**Mr. Spire**—The gas we are using is either argon or nitrogen. In the case of iron, nitrogen works well. In the case of steel, we started by using nitrogen. This gave us trouble with blowholes in the steel. Using argon, we had perfectly sound ingots. The flow was 5 liters a min and with that we had a strong agitation. We found no difference if the ladle was full or half empty as far as agitation was concerned, and we expect in large-scale developments, which will take place very soon, that the flow of gas will not be very much greater.

For iron, we have to use a fairly liquid slag and we have been trying lime and soda ash. We have been trying sodium carbonate and calcium carbonate and that was probably the best we have used. It worked very well. The weight was around 2 pct. For steel, we have been using various slags. We are planning to use some Perrin slags. The agitation we obtained is similar to the Perrin process, only we have a longer time for reaction taking place. The Perrin slag is a very good slag in connection with that. We have also been using a simple lime mixture with a certain amount of carbon in order to reduce the FeO content to a minimum.

**Mr. Larsen**—Do you have to have the gas flow on all the time that the metal is in contact with the porous refractor?

**Mr. Spire**—We prefer to have the gas going on all the time for various reasons. I may say that the refractory problem is not very simple. The way the porous plug is fixed to the bottom gave us trouble for several months, and I think we have straightened out this problem and the porous refractory can be used. We have used the same one for 30 heats in the 500 lb ladle. We do not have any more difficulty, but now we expect to run larger heats to see what we will get.

**C. H. Bacon** (*John Summers & Sons, Ltd., Shotton, Chester, England*)—What type of refractory is being used for the porous plug for the steel ladle?

**Mr. Spire**—We have been using brucite-type magnesium oxide.

## Solution Loss and Reducing Power of Blast Furnace Gas

by T. L. Joseph

DISCUSSION, A. H. Sommer presiding

**S. T. Killian** (*Johnstown, Pa.*)—This is one of the finest papers I have read. Tying in stoichiometric calculations with furnace performance and practice is a step which had to be taken sooner or later. The noteworthy difference between Dr. Joseph's type of calculations and regular blast furnace calculations is that the lb mol system is used as a basis. With the lb mol system, weights, volumes, and chemical reactions can all be expressed in the same equation.

In the paper, wind, ore, flux, and fuel are all expressed as lb or lb mols. Probably Dr. Joseph does not realize it, but the vague word coke appears only twice in the entire paper. Lb of C and lb mols of C are followed through reactions but the word coke appears only as 1560 lb coke per ton of pig and 1700 lb of coke per ton of iron. Obviously in order to understand furnace reactions, the coke should be expressed as lb or lb mols of C. Furnaces can also be compared more easily.

In some respects the paper is too thorough and too complete. The effects of the metalloids reduced into the iron upon the top gases represents a difference of less than 3 pct of the CO formed in the bosh. Due to the completeness of the calculations in relation to the CO/CO<sub>2</sub> ratio, this was included and was necessary. However, the exclusion might have enabled more furnace men to follow the lb mol system of calculations through the blast furnace to a better degree. By considering only irons of similar analysis, this part of the calculations might have been omitted. However, if this had been done, total rewriting of the paper later would have been necessary in order to make the work complete as it is now. It also would not have been nearly as authoritative.

In the paper, there appears the reaction:

Dr. Joseph states that he did not take this reaction into

consideration in any calculations pertaining directly to the paper. The probable reason for this is that although it contains all the main reacting top gases except N<sub>2</sub>, it is rather inflexible since it is monomolecular in relation to each of the reacting gases and does not tie in with the gasification of C.

Actually the reactions:

and the solution loss reaction:

tend to assume an equilibrium through the reaction:

which should be considered a balancing or equilibrium reaction. Reactions 2, 3 and 4 permit furnace conditions to balance with the CO/CO<sub>2</sub> ratio and H<sub>2</sub> formation. They tie in with the solution loss. Reaction 1 unites them chemically.

Probably the best calculation to make at this time would be to try to find the relative importance of the CO<sub>2</sub> from the flux and the H<sub>2</sub> in the dilution on an actual furnace gas analysis. For this purpose the Dobbscha-Carnegie-Illinois paper—"Effect of Sized and Sintered Mesabi Iron Ores On Blast Furnace Performance" is chosen. This paper was presented before the blast furnace section of the AIME in 1948. This represents the best large scale furnace operation available to me. Unfortunately the changes were brought about by beneficiation of the burden and not by changes on one burden.

In choosing the basis for the calculation in relation to the furnace, 100 mols of dry top gas is chosen. This leaves something to be desired inasmuch as the nitrogen basis is changing but I believe it will be better understood than any other type and it is the easiest to use.

The gas analysis and mols per 100 mol of blast furnace gas of the furnaces compared are:

|                 | Normal Ores |        | Prepared Ores |        |
|-----------------|-------------|--------|---------------|--------|
|                 | Pct         | Mol    | Pct           | Mol    |
| CO              | 26.57       | 26.57  | 26.17         | 26.17  |
| CO <sub>2</sub> | 12.33       | 12.33  | 12.40         | 12.40  |
| H <sub>2</sub>  | 2.30        | 2.30   | 1.60          | 1.60   |
| CH <sub>4</sub> | 0.13        | 0.13   | 0.13          | 0.13   |
| N <sub>2</sub>  | 58.67       | 58.67  | 59.70         | 59.70  |
| Total           | 100.00      | 100.00 | 100.00        | 100.00 |

Relative Amounts of CO<sub>2</sub> Evolved from Flux

In the paper, the distribution of the lb C per ton of iron in the top gases was given as follows:

|                       | Normal Ores | Prepared Ores |
|-----------------------|-------------|---------------|
|                       |             |               |
| CO                    | 1024        | 838           |
| Total CO <sub>2</sub> | 475         | 397           |
| Flux CO <sub>2</sub>  | 113         | 76            |

Since the amount of flux CO<sub>2</sub> in the total CO<sub>2</sub> is given, the flux CO<sub>2</sub> in the gas can be calculated directly:

|                                      | Normal Ores     | Prepared Ores  |
|--------------------------------------|-----------------|----------------|
|                                      |                 |                |
| Mol CO <sub>2</sub> in gas from flux | 113/475 x 12.33 | 76/397 x 12.40 |
| Mol CO <sub>2</sub> in gas from flux | 2.93 mol        | 2.37 mol       |

Relative Amounts of H<sub>2</sub> Formed

"Making, Shaping and Treating of Steel" by Camp and Francis contains the following notations on the blast furnace diagram:

- 875°C—much of the carbon dioxide is reduced by carbon
- 975°C—Combined water remaining is decomposed
- 1075°C—limestone is decomposed.

The evolution of CO<sub>2</sub>, the driving off of combined water, the H<sub>2</sub> formation, and the solution loss are tied in so closely that it may be impossible to separate them absolutely, but a start should be made. Probably the best way to correlate the H<sub>2</sub> formation from the efficient to the normal furnace would be through an H<sub>2</sub> to flux CO<sub>2</sub> ratio, since the normal furnace would eliminate the cooling and combined water farther down in the furnace with a consequential greater H<sub>2</sub> formation and a greater solution loss.

|                                                | Normal    | Prepared  |
|------------------------------------------------|-----------|-----------|
| Mol H <sub>2</sub> to mol flux CO <sub>2</sub> | 2.30/2.93 | 1.60/2.37 |
| Ratio                                          | 0.785     | 0.675     |

Thus if the furnace using normal ores decomposed as little water as the efficient furnace, the normal top gas would contain:

2.93 x 0.675 = 1.98 mol H<sub>2</sub>

This would leave:

2.30 - 1.98 = 0.32 mol H<sub>2</sub>

as excess H<sub>2</sub> decomposed in the normal furnace. Thus the 0.32 mol of H<sub>2</sub> would not have been formed if the normal furnace had worked as well as the efficient furnace. This excess can not be considered as being independent of the solution loss because it is probably tied in very closely with it. However it does represent excess H<sub>2</sub> in the gas and is so considered.

A breakdown of the calculations shows:

|                                  | Normal Ores |        | Prepared Ores |        |
|----------------------------------|-------------|--------|---------------|--------|
|                                  | Mol         | Pct    | Mol           | Pct    |
| CO                               | 26.57       | 26.57  | 26.17         | 26.17  |
| Combustion CO <sub>2</sub>       | 9.40        | 9.40   | 10.03         | 10.03  |
| Flux CO <sub>2</sub> (efficient) | 2.37        | 2.37   | 2.37          | 2.37   |
| Flux CO <sub>2</sub> (excess)    | 0.56        | 0.56   | 0.00          | 0.00   |
| H <sub>2</sub> (efficient)       | 1.98        | 1.98   | 1.60          | 1.60   |
| H <sub>2</sub> (excess)          | 0.32        | 0.32   | 0.00          | 0.00   |
| CH <sub>4</sub>                  | 0.13        | 0.13   | 0.13          | 0.13   |
| N <sub>2</sub>                   | 58.67       | 58.67  | 57.90         | 57.90  |
| Total                            | 100.00      | 100.00 | 100.00        | 100.00 |

In the above table based upon 100 mols of blast furnace gas and comparing the furnace using normal ores with the furnace when using prepared ores, we find 0.56 mol additional due to excess flux CO<sub>2</sub>, 0.32 mol additional due to excess water decomposition, and the remainder (with the type of calculations used) of 0.15 mol to be attributed directly to the solution loss reaction with no side reactions. However the solution loss reaction is tied in with the other reactions so closely that nearly 100 pct of the change must be considered as stemming from the carbon going into solution and the resulting interaction with H<sub>2</sub>O in the gaseous phase.

The figures seem to show that while the solution loss itself is masked by side reactions, the dilution of the N<sub>2</sub> is not diminished by them but is augmented by the resulting H<sub>2</sub> formation. Basically the principle of N<sub>2</sub> dilution due to the solution loss seems to work out better with the resulting additional water decomposed.

Attention is again called to the fact that the figures used do not represent a change in solution loss with no change in the burden. They represent a change from a burden of normal ores on a normal furnace to a burden of beneficiated ores being reduced more efficiently on the same furnace.

I regret that I can add nothing of value to Dr. Joseph's paper. By all standards it must be accepted as one of the finest papers produced.

Oxygen in Liquid Open-Hearth Steel—Oxidation during Tapping and Ladle Filling

by T. E. Brower, J. W. Bain, and B. M. Larsen

DISCUSSION, R. C. Solomon presiding

John Chipman (Massachusetts Institute of Technology, Cambridge, Mass.)—In tapping a heat of steel from the open hearth it is difficult, as the authors have pointed out, to distinguish between oxidation by air and oxidation by reaction with the slag. These effects could be distinguished and the oxidation due to air more closely identified if the same method were applied to tapping electric furnaces. Here the slag can be made reducing and the bath presumably uniform, thus changes due to air oxidation from furnace to ladle should be capable of more exact determination.

It should be pointed out also that if the amount of oxygen picked up from the air is as great as the authors have indicated, there is little incentive to produce an entirely deoxidized bath in the electric furnace. The use of a reducing slag for controlling alloy elements and for desulphurization is understandable. But from the standpoint of deoxidation its effect would be entirely lost in tapping if the reaction with air is comparable with that reported here. C. H. Bacon (John Summers & Sons Ltd., Shotton, Chester, England)—I was particularly interested to see the films of the tapping streams, as we have taken some high speed films of the teeming streams between

the ladle and the mold. The original purpose of taking the films was not connected with oxidation, but we found that the form of the metal streams varied greatly; some of the streams were relatively compact, whereas others were very ragged. I should like to ask Mr. Larsen for his views on the degree of oxidation that takes place between the ladle and the mold, and to what extent this might be influenced by the form of the stream.

**N. R. Arant** (*Titanium Alloy Manufacturing Co., Pittsburgh*)—The results and motion picture studies in this paper indicate that perhaps a great deal can be learned if the oxidizing and nitrifying effect of air during tapping is accentuated. One way to observe this effect would be to consider the elements which more readily react with air, namely; aluminum, titanium, and zirconium. Since steels containing both titanium and aluminum are in widespread production, these would be the ones to test. The more common grades produced in the arc-electric furnaces are: 321 (18-8 Ti), 17 pct Cr-Ti, 5 pct Cr-Mo-Ti and 19-9DL.

Both titanium and aluminum have a strong affinity for nitrogen as well as oxygen; therefore, if the steels mentioned above can be tapped with a minimum of contact with air, a much cleaner final product might result, with fewer titanium nitride and aluminum oxide nonmetallic inclusions. Furthermore, since ferro titanium and aluminum are expensive, there is the possibility of a considerable saving in the cost of producing the ingots.

In comparing standard tapping methods with the tilted-ladle method while considering the active elements mentioned above, it may be possible to more accurately calculate the volume of air which comes in contact with the steel during tapping.

To obtain accurate data during tapping, I believe it is necessary to obtain representative samples of metal and slag before tap, from the ladle, and during teeming. If good samples are used it seems logical that a clearer picture can be obtained regarding the oxidizing and nitrifying of alloying elements during tapping and ladle filling.

**R. K. Kulp** (*Electro Metallurgical Co., Division of Union Carbide & Carbon Corp., Pittsburgh*)—Metallurgists have made frequent reference to the problems involved in determining the reactions which occur during the tapping of open hearth heats. The authors of this paper are to be commended for developing the "air oxidation" method of determining the amount of reaction taking place during tapping and ladle filling.

This paper was presented before at the 1950 Open Hearth Conference, and at that time a discussion was presented by Mr. Tenenbaum. He offered data which indicated that the degree of air oxidation was less on heats which were blocked than on heats which were tapped open. In his rebuttal, Brower failed to agree with Tenenbaum's statement that "losses of elements dissolved in steel prior to tap are generally small." Do the authors have any specific information on air oxidation of blocked vs. open heats which would indicate a difference due to initial deoxidation?

**B. M. Larsen** (authors' reply)—Dr. Chipman's idea of separating slag and air oxidation by using data from electric furnace heats with reducing slags at tap is a logical one. We have obtained data on a few such heats but the method of estimating oxidation by difference, from alloy materials balances, gave inconclusive results. Both the quiet metal bath and the tap stream tend in this practice to be quite inhomogeneous and the sampling problem is an almost impossible one. Thus we feel that such evidence is not nearly as good as that given in the paper, which indicates a relatively negligible effect from reaction with slag. These data on electric steel heats did indicate a large loss by air oxidation, and in spite of the uncertainty caused by variable analyses and the difficulties of representative sampling, we believe that much of this oxidation loss is real, and that with respect to the final ingot, at least, deoxidation is essentially dependent, not on the

reducing slag, but on the deoxidizing alloys just as it is in the open hearth. Thus, the tendency for much electric steel to be cleaner than open hearth remains about as much of a mystery as ever from any data we have obtained to date.

We did try to obtain the "representative samples" listed by Mr. Arant. However, the sampling here is a problem at best. Fortunately, the metal in open hearth baths is usually well mixed on heats tapped open. Blocked heats show somewhat more variability in tap stream composition.

We cannot give a definite answer to Mr. Bacon's question about oxidation between ladle and mold, although a few inconclusive indications from inclusion counting vs. various controlled and uncontrolled teeming conditions did indicate the probable existence of a relatively smaller effect which we rather believe did tend to increase inclusion content in the ingot. As noted in our comments on "oxidation effects and steel quality" in the paper, we suspect that certain factors are present which are perhaps not yet even recognized or at least are poorly understood. At least it appears that ragged or spraying teeming streams are worth taking some pains to avoid.

For a really conclusive answer to Mr. Kulp's question about relative alloy losses between blocked and open heats, comparative data on groups of 20 to 30 or more heats in the same grades of steel should be used. The pattern of variability in tapping conditions is so haphazard that results on smaller groups are not very reliable unless the factors involved have a large effect. However, the following data are on three small groups of killed heats, all of them medium to high carbon, mostly around 0.50 to 0.60 pct C at the platform:

|                                | No Block,<br>Tapped on<br>Carbometer—<br>Fine Grain | Blocked Heats   |                   |
|--------------------------------|-----------------------------------------------------|-----------------|-------------------|
|                                |                                                     | Fine<br>Grained | Coarse<br>Grained |
| No. of heats averaged in group | 7                                                   | 8               | 10                |
| Loss, lb per ton, Mn           | 1.67                                                | 1.85            | 1.19              |
| Loss, lb per ton, C            | 0.30                                                | 0.66            | 0.50              |
| Loss, lb per ton, Si           | 0.80                                                | 0.66            | 0.97              |
| Loss, lb per ton, Al           | 0.85                                                | 0.68            | 0.45              |
| Total alloy loss, lb per ton   | 3.62                                                | 3.85            | 3.11              |
| Lb oxygen per ton, external    | 2.58                                                | 2.55            | 2.38              |

Differences here are small, especially in terms of the indicated weight of oxygen reacting (from sources outside of the metal, presumably from air). The coarse grained heats had less aluminum loss, which is reasonable, and less manganese loss most likely because the oxygen happened to react more with the silicon. In total alloy losses, one group of blocked heats was higher, the other lower, than the heats tapped open with no furnace block. As shown by Brower in an earlier discussion<sup>6</sup> of this same paper that although aluminum and silicon and perhaps manganese (when high in fines) probably are all lost to some extent by floating and burning at the surface (aluminum may also react to some appreciable extent with ladle lining surfaces), yet quite large losses can occur from alloys definitely dissolved in the iron solution by some external effect which, directly or indirectly, would seem to be from atmospheric oxygen. Such an effect, almost obviously, is independent of any blocking or other occurrence in the furnace before tap.

As a purely practical matter, blocked heats with much of the alloy additions made in the furnace before tap probably do have somewhat lower average losses after tap, but the added losses in the bath before tap are such that total alloy loss is generally equal to or greater than in heats tapped open. That blocking improves quality is at least very doubtful, and it is certainly wasteful of alloys and of furnace time. Though sometimes needed for other practical reasons, in the writer's opinion, the blocking of heats should be avoided as much as possible.

## Metallographic Study of the Martensite Transformation in Lithium

by J. S. Bowles

DISCUSSION, M. Cohen presiding

**J. W. Christian** (*The Inorganic Chemistry Laboratory, Oxford, England*)—I was very interested in Dr. Bowles' results on the suppression of the transformation by solid films of alcohol or propane. The transformation in cobalt, which is also martensitic, can be explained by a mechanism involving the reflection of "half dislocations" down a series of atomic planes.<sup>12</sup> This reflection process is similar to that considered by Frank<sup>13</sup> for plastic deformation on a single slip plane and, as he pointed out, reflection would be impossible if the metal were immersed in a liquid of higher density. It seems possible that solid films of alcohol have a similar effect on the lithium transformation.

Reflection should also be possible at a grain boundary, though a higher kinetic energy of the dislocation, and hence a lower temperature would be required. As Dr. Bowles used coarse grained polycrystalline speci-

mens, transformation on cooling should still have occurred in grains which did not form part of the outside (free surface) of the metal. This may account for the X-ray lines of the low temperature phase which were found. There is thus the interesting possibility that in a polycrystalline specimen a liquid, or in some cases a solid, film of material of comparable or higher density will lower  $M_s$ , while in a single crystal it should suppress the transformation completely.

In the case of cobalt it is necessary to find a dense liquid which will not react with the metal at the transformation temperature. The most promising liquid appears to be pure lead, but it is very difficult to devise a method of investigating whether or not this does suppress the transformation.

## Crystal Structures and Transformations in Indium-Thallium Solid Solutions

by Lester Guttman

DISCUSSION, M. Cohen presiding

**A. H. Geisler and D. L. Martin** (*General Electric Research Laboratory, Schenectady, N. Y.*)—We were rather interested to note the author's conclusion that

the cubic to tetragonal transformation may be of the second order, for we have been able to show that the order-disorder transformation in an analogous alloy system is a first-order transformation with a discon-

tinuous change in composition, rather than the frequently assumed second-order type.<sup>14</sup> Although it seems questionable whether the heterogeneous equilibrium of a martensitic reaction may be described, the author has attempted to define the reaction type, and on this basis we should like to examine the evidence further. In our work we have stressed the importance of establishing equilibrium, which may require hundreds of hours at relatively high temperatures. It is our contention that lack of equilibrium leads to results that suggest the so-called second-order type of transition. Here the author has attempted to attain equilibrium in time intervals of slightly more than a few minutes. We would like to know whether the transformation was studied using any appreciable annealing periods in those cases in which two-phase structures were merely assumed to be nonequilibrium.

In regard to the supposed continuity of volume shown by Fig. 3, if the curve were drawn through the data points for the 12½ and 18 pct alloys, there would be a discontinuity between 18 and 19 pct Tl. This would suggest a first-order transformation with a two-phase field at these compositions and the specified annealing temperatures of 105° to 135°C. These conditions agree with the boundary in the phase diagram, Fig. 9, but require that there should be two boundaries. On the other hand, the data in Table I appear to apply to the structure at room temperature and if this is so, it seems inconsistent to assign any special merit to the data plotted by full circles which are specified as "more thoroughly annealed specimens" where the annealing refers to 105° to 135°C and not room temperature. Thus it is questionable whether these data could support a conclusion regarding the type of reaction.

The author has observed that the data indicate no two-phase region wider than about 0.5 pct Tl at room temperature. This hardly seems an adequate basis for concluding that the cubic-tetragonal transformation is one of the second order rather than of the first order. We are sure that the author considers the liquid to solid transformation in the indium-rich alloys as the first-order type, yet the phase diagram, Fig. 9, fails to show width in the liquid plus solid field for alloys up to 30 pct Tl. Naturally, the minimum accounts for zero width at one point only. In fact there are many binary systems in which the two-phase field between a liquid and solid solution is very narrow or has escaped detection. Similarly the fields between two solid phases such as ferrite plus austenite in most of the  $\gamma$  loop forming systems of the iron-rich alloys are narrow. The A.S.M. Handbook shows a 0.1 pct maximum range for Fe-V. The two-phase fields between the ordered and disordered phases in Co-Pt alloys with 18 to 26 pct Co are less than 0.5 pct Co in width but still are detectable. In this case we found that electrical resistance measurements were most convenient for determining boundaries of the two-phase fields.

Since the two-phase region, if it exists between cubic and tetragonal phases in In-Tl alloys, is narrow, additional evidence is needed before the type of transformation can be definitely established. Perhaps, as the author noted, highly precise measurements of the heat capacity are needed to distinguish a first from a second-

order transformation, but there may be some doubt that the sensitivity of thermal methods is as good as that of currently used techniques. Apparently the only practical deciding test for a two-component system is whether or not there is an "unambiguous" two-phase region. The test has not yet yielded conclusive results for many systems including the order-disorder reaction in  $\beta$  brass.

**L. Guttman** (author's reply)—The comments of Drs. Geisler and Martin are valuable for drawing attention to portions of the paper which are obscure, partly for reasons of language. It is hoped that the following formulation will clarify the basis for my conclusions, which remain essentially unchanged.

The evidence summarized in Table II is that the cubic-tetragonal transformation, both on heating and cooling, is complete in a temperature interval of less than 10° centered on the line drawn in Fig. 9. Hence the equilibrium boundary or boundaries must lie within this region, which is about 0.5 atomic pct wide at all temperatures, the slope of the line being roughly 20° per atomic pct Tl.

The effect of uniform long annealing is to decrease the fluctuations of a few hundredths of 1 pct in the lattice parameters apparently caused by severe deformation, which would otherwise obscure the changes associated with the transformation itself. The choice of the phrase "approach to equilibrium" to describe this process of stress relief was unfortunate. However, aside from the uncertainties due to this effect and to the hysteresis between the direct and reverse transformations, the question to be decided from Fig. 3 is whether there is any discontinuity in volume in the vicinity of 22.7 pct Tl, where the structure changes from tetragonal to cubic at room temperature; the annealing temperature itself is immaterial as long as it is high enough; since the high temperature structures cannot be undercooled more than a few degrees, see also Fig. 8.

Shortly after the present work was submitted, there appeared a similar study by Makarov<sup>15</sup> which agrees in finding no two-phase region between the cubic and tetragonal forms, and places the boundary at about 25 pct Tl at room temperature.

The relevance to the present case of arguments based on other systems is of course questionable; moreover, they should not be allowed to confuse the generally valid criterion that the absence of a two-phase region means that the transformation is of higher order than the first, and vice versa. In particular, examination of the data of Valentiner,<sup>2</sup> which could not be adequately shown in Fig. 9, will reveal definite separation of liquidus and solidus between 0 and 12 pct Tl, even in this very unfavorable case of a minimum melting point only 4° below that of pure In.

Finally, the intention of the comment in the footnote (p. 1477 of the paper) was obviously not to recommend thermal methods for characterization of transformation order in solids.

## Crystallography of Cubic-Tetragonal Transformation in the Indium-Thallium System

by J. S. Bowles, C. S. Barrett, and L. Guttman

DISCUSSION, M. Cohen presiding

**A. H. Geisler and D. L. Martin** (*General Electric Research Laboratory, Schenectady, N. Y.*)—The authors have very nicely demonstrated that the observed data

agree much better with a proposed double-shear mechanism than they do with an assumed twinning mechanism. Reference is made to our results on an analogous alloy, Co-Pt in which a disordered cubic phase transforms to an ordered tetragonal phase.<sup>14</sup> True, our con-

Fig. 14—Array of poles for tetragonal structure formed by transformation mechanism proposed by the authors (left) and that for nucleation and growth on  $\{111\}$  planes with first generation twinning (right).

clusion that the tetragonal lattice has the same orientation as the cubic lattice is only an approximation. Actually coherent platelets on  $\{110\}$  planes require that some of the tetragonal axes make angles of  $27'$  to  $43'$  (depending on  $c/a$  ratio) with cube axes according to the orientation relationship  $(110)_D // (101)_O$  and  $[001]_D // [010]_O$ .

We should like to suggest that a better assumption might be made for evaluating the twinning mechanism in In-Tl alloys rather than assuming that the original

cubic crystal becomes tetragonal by simple expansion along one cube axis and contraction along the other two, without change of orientation. In this case coherency on  $\{111\}$  planes appears to be promising. That is, a probable mechanism to test the twinning hypothesis would be to assume that the tetragonal phase formed from the cubic phase by growth of platelets on  $\{111\}$  planes with the tetragonal lattice being attained by adjustments in the spacing and atomic positions of  $\{111\}$  cubic planes. It is interesting to note that this

Fig. 15—Banded structure in unrepresentative surface layer of 48 atomic pct Co-Pt alloy disordered at  $950^\circ\text{C}$  then cooled to  $822^\circ\text{C}$  and held 25 hr and water quenched. Ordered plus disordered phases. X500.

Area reduced approximately 40 pct for reproduction.

Fig. 16—Widmanstatten pattern (left) and striations (right) in 54 atomic pct Co-Pt alloy held 50 hr at  $728^\circ\text{C}$ . Ordered plus disordered phases. X500.

Fig. 17—Striations in fully ordered sample of 54 atomic pct Co-Pt alloy held 1000 hr at  $600^\circ\text{C}$ . X100.

Fig. 18—Surface deformation in In-Tl alloy. Oblique illumination. X75.

Fig. 19—Same as Fig. 18, electropolished and electroetched. Area Figs. 18 and 19 reduced approximately 40 pct for reproduction.

mechanism provides a pole figure for the 20.75 pct Tl alloy, Fig. 14, in which the central portion is identical to that for the proposed double shear mechanism. Poles for the initial platelets of the tetragonal phase and first generation twins only are shown. Possibly the outer poles represent twins that do not relieve transformation stresses and thus do not occur. It might be profitable to search for these and for a Widmanstätten pattern of platelets of the tetragonal phase on  $\{111\}$  planes of the cubic phase if samples could be prepared for the two-phase structure with microscopically resolvable particles and without the structure being obscured by the banded markings.

The authors have suggested that the ordering reaction in alloys such as Co-Pt, Fe-Pt, and Cu-Au might progress by a double shear mechanism on the basis that striated microstructures are observed for these alloys also. We should like to examine the comparison further, particularly in regard to Co-Pt where we have made a rather extensive study of the microstructures. In only one sample have we observed the clear-cut main bands with sublamellae shown by Fig. 15 analogous to the structure reported by the authors for In-Tl alloys. Here all bands are parallel to  $\{110\}$  planes and the subbands are on planes at angles of  $60^\circ$  to the plane of the main band, and with evidence of interpretation. The sample which was disk-shaped as cut from  $\frac{1}{4}$  in. diam rod exhibited a transformed zone only around the cylindrical surface (see Fig. 7a, reference 15). The sample had been held at a temperature above the transformation range for the bulk alloy but below the range for the presumably impure surface layer. This sample provides an insight into the mode of lateral growth of the main bands. These usually occurred in pairs with a W-shaped edge possibly due to tilting in opposite senses as for In-Tl alloys, but frequently single main bands were observed to be growing in the untransformed matrix as in Fig. 15. The sloping surfaces at the V-shaped edges are parallel to some high order plane such as  $\{780\}$ . Possibly this should be considered as the "habit" plane rather than the  $\{110\}$  planes to which the irregular edges of the fully developed subbands are parallel.

Usually the striated structures in Co-Pt alloys are

not as clearly defined as that shown above. The more prominent striations are apparent when the transformation is conducted at temperatures in or near the equilibrium temperature range. The striations may occur in irregular nodules bounded by no distinct main bands suggesting that the "first shear" is unnecessary. In one sample a banded structure was observed in some grains (Fig. 6d, reference 14) whereas others had a clearly defined Widmanstätten pattern of platelike particles of the ordered phase in the disordered matrix (see Fig. 6c, reference 14 and Fig. 7d, reference 15). It is believed that the latter is the primitive mechanism of the transformation and this is obscured in grains so oriented with respect to their neighbors that the self-deformation process may operate. The two types of structures in adjoining grains are shown by Fig. 16. Recent analyses show that the striations also correspond to traces of  $\{110\}$  planes rather than to the previously reported  $\{111\}$  planes.<sup>14</sup> When ordering is conducted at temperatures such as  $700^\circ$  and  $600^\circ\text{C}$ , which are below the equilibrium temperature range, the striated structure is less prominent (see Figs. 7c and 7d, reference 14). Nodules of parallel bands are no longer prominent and the bands appear wavy and intersect each other very frequently as in Fig. 17. The microstructure is more similar to those which have been reported for Cu-Au<sup>5</sup> and Fe-Pt<sup>4</sup> alloys than it is to that reported for In-Tl alloys. In Co-Pt alloys the cubic phase can be retained by quenching and the transformation can be promoted isothermally at subcritical temperatures. Under these conditions the striations appear after the start of the transformation and continue to become more prominent long after completion of ordering according to X-ray data on the same metallographic samples which lend support to the hypothesis that they represent a mode of stress relief rather than the primary transformation. Finally striations are faint or absent on ordering at  $500^\circ\text{C}$  where most prominent manifestation of the transformation is the formation and growth

<sup>14</sup> J. B. Newkirk, A. H. Geisler, D. L. Martin, and R. Smoluchowski: *Trans. AIME* (1950) 188, p. 1249, *JOURNAL OF METALS* (October 1950).

<sup>15</sup> J. B. Newkirk, R. Smoluchowski, A. H. Geisler, and D. L. Martin: *Journal of Applied Physics* (April 1951).

of recrystallized nodules at grain boundaries (see Figs. 7a and 7b, reference 14).

Thus we are inclined to believe that the major mechanism of the transformation in Co-Pt alloys is by the Widmanstätten type process in which platelets of the tetragonal phase are nucleated and grow parallel to {110} planes of the cubic matrix and that the major source of striations is the self-deformation process by twinning or slipping in which strains are relieved in the course of or subsequent to the transformation.

**L. Guttman** (authors' reply: Due to the absence from the United States of the other authors, one author is responsible for the reply)—It is difficult to see why an alternative to the double-shear mechanism should be sought, since it appears to account satisfactorily for all the observations. The proposed mechanism is moreover in conflict with several critical features:

1—Presumably, a given colony of main bands consists of the tetragonal material formed by adjustments within a particular (111) plane and one of its first generations twins; but this gives only two orientations of the eight found as shown in Figs. 7 and 8, when a grain has a single set of main bands.

2—The subbands are not explained, since if they

were second-generation twins the pole clusters could not correspond to observation.

3—On the proposed mechanism, there is no way to account for the observed mode of development, which is invariably the propagation of a (110) interface into the cubic material. In the paper, it was assumed that the bands appearing on a smooth surface were identical with the "main bands" revealed by electropolishing and etching, and hence represented traces of (110) planes. Although any other possibility seemed unlikely, we have since verified their identity by comparison in several cases of the surface distortion with the microstructure of the material immediately below, as shown by Figs. 18 and 19. It should be noted especially that both members of a pair of main bands are tilted with respect to the original cubic surface (Fig. 5, reference 1), and hence that at least part of the transformation must occur homogeneously.

4—It seems rather perverse to describe the banded markings as "obscuring" the structure when in fact they have served so well in elucidating it.

Apparently the mechanism of ordering in Co-Pt alloys is more complex than suggested by us on the basis of earlier information.

## Interface and Marker Movements in Diffusion in Solid Solutions of Metals

by Luiz C. Correa da Silva and Robert F. Mehl

DISCUSSION, A. H. Geisler presiding

**A. D. Le Claire and R. S. Barnes** (*Atomic Energy Research Establishment, Harwell, Didcot, Berks., England*)—This much awaited paper admirably confirms that the Kirkendall effect is a true diffusion phenomenon and likely to be found in all diffusing systems. The most likely explanation put forward so far to account for the shift of interface is that the two components of the system, diffusing in opposite directions, do so with unequal rates so that there is a net loss of material from that half of the diffusion zone rich in the more rapidly diffusing component. This loss is accompanied, and at least partly compensated for, by a closing up or decrease in volume of this latter half of the diffusion zone and an expansion of the other half so as to tend to keep constant the overall volume per atom. This is manifest as a movement of the original interface. If this is a true picture of what is taking place then there are at least two important matters requiring further study.

1—The quantitative relating of the observed shift with the independently measured separate diffusion coefficients of the two diffusing species.

2—A detailed study of the mechanism and characteristics of the closing up process.

We would like first to make a few remarks pertinent to these topics. In connection with the first of these, it is a pity that more and detailed measurements were not made on the Au-Ag system, the only one for which the separate diffusion coefficients of the two species have been measured.<sup>18</sup> One of us (A. D. Le C.) has calculated from Johnson's results the shift to have been expected in samples D.2 and D.3. Darken<sup>4</sup> showed that the velocity  $v$  with which the markers move is related to the separate diffusion coefficients  $D_{Au}$ ,  $D_{Ag}$  by the equation:

$$v = (D_{Ag} - D_{Au}) \frac{\partial N}{\partial x}$$

where  $\frac{\partial N}{\partial x}$  is the concentration gradient at the markers. Under certain conditions,<sup>4, 20</sup> it can also be shown that:

$$v = \frac{Xm}{2t}$$

where  $x_m$  is the total marker shift after time,  $t$ :

$$x_m = 2t (D_{Ag} - D_{Au}) \frac{\partial N}{\partial x} \quad [9]$$

Johnson measured  $D_{Ag}$  and  $D_{Au}$  in a chemically homogeneous alloy and so his reported figures represent the true or ideal diffusion coefficients<sup>21</sup>; the same quantities in eq 9 represent the actual diffusion coefficients as would be measured in the presence of a chemical concentration gradient, so we need to multiply Johnson's reported values of  $D_{Ag}$  and  $D_{Au}$  by the

thermodynamic factor  $\left(1 + \frac{\partial \log \gamma}{\partial \log N}\right)$  before insert-

ing them in eq 9.  $\gamma$  is the activity coefficient of Ag at the concentration prevailing near the markers which we shall assume to be  $\sim 50$  pct. The values of the thermodynamic factor for  $N = 0.5$  and the temperatures at which D.2 and D.3 were annealed were obtained from thermodynamic data quoted by Darken.<sup>4</sup>

$\partial N / \partial x$  was computed from the coefficient of interdiffusion of Au and Ag given by Johnson on the assumption that in the samples D.2 and D.3, the concentration distance curve could be represented by the standard equation:

$$N = \frac{N_0}{2} \left\{ 1 - \phi \left( \frac{x}{2\sqrt{Dt}} \right) \right\}$$

$N_0$  is the original difference in concentration between the two halves of the couple, and  $\phi$  is the error or probability function.

$\partial N / \partial x$  at  $x = 0$  is then given by:

$$\partial N / \partial x = \frac{N_0}{2\sqrt{\pi Dt}}$$

and we assume that this represents the concentration gradient at the markers, although it is probable that the figure is slightly high.

When all the appropriate quantities are inserted in eq 9, we find that the expected shifts are: for D.2, 0.0134 cm and for D.3, 0.0119 cm.

The agreement between these results and those

Fig. 62 (above)—Voids in diffusion zone of Cu/Ni couple diffused at 1030°C for 68 hr in hydrogen. Mechanically polished. X270.  
Area reduced approximately 75 pct for reproduction.

Fig. 63 (right)—Cu/Ni couple diffused at 940°C for 66 hr in argon. Electrolytically polished. X270.  
Area reduced approximately 70 pct for reproduction.

actually found by da Silva and Mehl is very satisfactory. It indicates that the marker movement is predominantly determined by the difference in diffusion rates; other possible sources of movement will probably only play a secondary role. Further work along these lines is much to be desired.

An important result which touches upon the closing up process is that "the Matano interface agrees with the original interface." The validity of this statement is important because it is used as evidence that porosity is negligible, although the authors did in fact find porosity. But it seems to be contradicted by the results on samples B 22-I (Fig. 17), B 39-I (Fig. 19), and B 46 (Fig. 22) where the shifts as measured using the diffusion curve method are in the opposite direction to those given in the results for the type of couple concerned. Also in this connection the result of the lateral marker experiment suggests that the shifts obtained by the diffusion curve method should be modified, so spoiling the agreement between Matano interface and original interface positions. The results of the lateral marker experiment is most interesting for not only did these markers not move together as a result of the unequal diffusion flow but, although the lattice parameter in the locality of the markers decreased, their distance apart remained constant. This result can only mean that the number of atomic planes in the direction of diffusion must increase to maintain the distance constant, and as the authors say there must be a restraint to prevent the brass from contracting in directions at right angles to the diffusion flow; this would be expected when the diffusion flow is restricted to one direction as suggested by C. S. Smith in his discussion of the paper by Smigelskas and Kirkendall.<sup>1</sup> In the light of the result of this lateral marker experiment Smith's remarks are more pertinent than before and so the shift due to lattice parameter change should be three times that plotted on the curves relating shift to  $\sqrt{t}$  or the Matano area, since the volume changes re-

sulting from the lattice parameter change can only be relieved in the direction of diffusion. If this correction is made then all the points on these plots lie under a line which is the sum of the corrected curve for the lattice parameter shift and the maximum possible shift with the remarkable exception of the results for Cu/Sn couples.

Using the same result that the movements are restricted to the diffusion direction, the lattice plots (Figs. 13 to 24) should be modified, if the effect of the change in lattice parameter is not to be included in shifts obtained by the diffusion curve method. A rough calculation in the case of the sample B 39-I, for example, would move the Matano interface to a position much nearer the ordinate. As the shift given by this diffusion curve as it stands is in the wrong direction, this correction improves the result. In all cases the correction will move the Matano interface toward the small atomic component and so increase all the shifts as calculated

from the diffusion curve (apart from those in the wrong direction, already mentioned, which will be reduced). The correction is only of importance in those couples where the Kirkendall effect is small.

It would be interesting to compare figures from the foil bend method and the diffusion curve method, for from the difference the volume occupied by voids can be estimated.

The authors of this paper found porosity in only the diffusion zones of the Cu/ $\alpha$  brass and the Cu/Al bronze couples. One of us (R. S. B.) has found quite unmistakable voids occurring in the diffusion zone of Cu/Ni couples on the copper-rich side of the original interface. Similar voids to those reported were also found in Cu/ $\alpha$  brass couples on the zinc-rich side of the original interface.

Fig. 62 shows the shape of these voids in a Cu/Ni couple which has been diffused at 1030°C for 68 hr in a hydrogen atmosphere. It may be observed that most of these voids have some straight faces which suggests that the voids are polyhedral in shape. Fig. 63 shows a similar couple, in this case diffused at 940°C for 66 hr in an argon atmosphere and given an electropolish which destroys the shape of the voids but reveals their position relative to the original interface, which is made visible by the impurities occurring in the welded join. Both micrographs show that the voids form in a fairly definite plane at right angles to the diffusion flow and, as reported for the brass couples, at some distance from the original interface, but in the diffusion zone.

In Fig. 63 the technique of outlining a concentration contour on the nickel-rich side of the original interface, as previously described,<sup>22</sup> has been used to show the preferential diffusion of the copper along the nickel grain boundaries, and in these regions where the extra diffusion has taken place the marker interface can be seen to bulge towards the copper-rich side, so giving a larger Kirkendall shift in these regions.

The grain boundaries in the diffusion zone pay little attention to the marker interface in these Cu/Ni couples, but many of them are irregular and suggest strain in this region.

The fact that visible voids are formed in certain cases suggests that the large number of vacancies involved do not necessarily condense only by the mechanism proposed by the authors. There are several possible ways in which the vacancies might condense: 1—by diffusing to the surface, 2—on dislocations with a Taylor-Orowan characteristic (within the crystal or at grain boundaries), 3—on impurities of a macroscopic or even atomic nature, 4—initially probably as plate-like voids which soon collapse producing a dislocation ring as the authors suggest, and 5—as voids which do not collapse, probably of a roughly spherical shape.

Mechanisms 1, 2, and 4 do not lead to the formation and growth of visible voids, but it is conceivable that 3 and 5 might do so, and these may be operating in those cases where voids are seen. The presence of gas dissolved in the metal might seriously affect the behavior, subsequent to their formation, of the voids produced by any of the mechanisms 3, 4, or 5 but particularly in cases 3 and 5. Once a cavity is formed by any of these mechanisms, gas present in solution in the metal might diffuse into the cavity and prevent its collapsing, when in the absence of any gas it might have done so. Once stabilized in this way, the cavities might then grow to a visible size by condensation at them of further vacancies. The authors mention the importance of gas reactions as a possible complicating feature of this type of experiment and say that this can be avoided, but without saying exactly how. In view of the existence of a porosity in some samples but not in others, it would be interesting to know if an analysis of the gas content of the samples used by the authors is available. High metallic purity of the samples seems to be no guarantee of the absence of a gas reaction as evidenced by sample C.17. It is possible also that the existence of a porosity in our Cu/Ni samples and its reported absence in those samples used by the authors may be connected with their possible different gas contents.

In connection with Fig. 39, if the values of  $D$  previously found by Rhines and Mehl, are "highly approximate," why were they included in this figure? If only the authors present results are used in calculating  $Q$ , the values at high zinc concentrations are considerably raised, to about 40,000 cal per mol, and are in much closer agreement with previous measurements of  $Q$  in high zinc  $\alpha$ -brasses.

**L. C. Correa da Silva and R. F. Mehl** (authors' reply)—The discussion of Messrs. A. D. LeClaire and R. S. Barnes is most interesting, and deserves detailed reply.

Their calculations of marker shift and the agreement of this with the observed shift in the Ag-Au system is encouraging. There are limitations to the application of the calculation, for the data are not quite adequate for the purpose: the data of Johnson are for the 50:50 composition; and the thermodynamic data employed were selected for this composition; the marker, however, surely does not follow this composition, but one at a much higher percentage of Ag,—the agreement

found is thus presumably somewhat fortuitous. The "pity" in all research lies in its necessary incompleteness. It would be good to expand the data for the Ag-Au system, for marker shift, as well as for the separate diffusion coefficients by the use of tracers—it is a bit surprising that Johnson's work has not been extended.

Porosity in diffusion samples is often a fugitive, evanescent phenomenon. Although invariably observed in Cu/ $\alpha$  brass couples, its occurrence in other couples is sometimes debatable. In most cases it is slight to the point of uncertainty; etching exaggerates it (and may change the geometry of the separate pores, as may polishing), and through the formation of etch pits may deceptively simulate it. Certainly even in Cu/ $\alpha$  brass couples the total volume of porosity is small, judging from direct observation, apart from the argument arising in the concurrence of the original interface and the Matano interface. It should be noted in passing that the contradictory results on samples B 22-I, B 39-I, and B 46 should not be given much weight; the concentration range is small, and small errors in chemical analysis disturb the results in these systems; these curves are less reliable than the others. No determinations of "gas" content were, nor could have been made on samples such as those employed. Obvious swelling was observed in some samples (subsequently discarded), originating in the generation of internal blowholes. Inert gas ambients are always to be preferred for this reason. The "foil-bend," the "reference-to-foils," and the "diffusion curve" methods avoid the difficulties which gas or any porosity creates in analysis of marker shift.

The use of lattice units did appear to us to be fundamentally justifiable, apart from any consideration of marker shift; the point which Messrs. Le Claire and Barnes make received much attention in our thinking, but in view of the fact that we have but one measurement of lateral dimensions (made late in our work) it hardly seemed useful further to develop the lattice unit scheme—or any other framework. The matter of changes in lateral dimensions in samples such as ours and in others of differing geometries ought to be studied in detail.

The new observations reported on Cu/Ni couples are most interesting. The greater marker shift near grain boundaries, where diffusion is greater, is of course to be expected. Etching techniques such as those employed have been reported before; several instances were noted in 1936 Institute of Metals Lecture, though the combination of this technique with observation of marker movement is new and might be further exploited. In our case, the grain sizes were so very large that the marker movements recorded must have been near to those for single crystals.

The five possible ways in which vacancies might condense, as suggested, have all been considered. The first seems unlikely for the reasons given in the text. The whole question of mechanism of vacancy condensation is still worthy of thought and resultant experiment; it surely is not yet satisfactorily resolved.

The text with reference to Fig. 39 must have been misread. The expression "highly approximate" was used in reference to the  $Q$ -values of Rhines and Mehl; at high temperatures, the  $D$ -values, as reported here, agree with those of Rhines and Mehl quite well, as Fig. 38 demonstrates.

## Torsion Texture of Copper

by W. A. Backofen

DISCUSSION, J. R. Low presiding

**W. R. Hibbard, Jr.** (*General Electric Co., Schenectady, N. Y.*)—Dr. Backofen's pole figures showing the deformation texture of severely twisted polycrystalline copper are very interesting because of the large shear strains, the difficulty of interpretation, and their correlation with flow.

It is my opinion that the interpretation of the pole

figures given in the paper is not self-consistent. It is not reasonable to have one of the four octahedral poles of a given orientation in an area of high intensity, while the others are in areas of low intensity as is the case in Fig. 6. If the texture is (112)  $[11\bar{1}]$ , and a density of eight occurs in the longitudinal direction, then a density of eight must occur in the other positions for the octahedral poles of that orientation, or that is not

Fig. 10—Single crystal of  $\alpha$  brass with (111) plane perpendicular to the torsion axis (axis vertical, plane horizontal) given 1.68 shear strain in torsion showing slip lines and deformation bands. Polished prior to twisting. X10.

the orientation involved. The most consistent interpretation of Fig. 6, in my opinion, is a duplex texture as follows:

111 direction parallel to the longitudinal direction with a random orientation of poles perpendicular to that direction (similar to the wire texture)

(110) [001] orientation superimposed

This interpretation will account for the three high density octahedral areas and not require octahedral poles in low density areas. It can be critically evaluated by examining the (002) reflection ring and determining whether or not there are any grains actually oriented with their 001 poles parallel to the longitudinal axis. For both of these orientations slip systems are suitably oriented with slip directions in the direction of maximum shear stress to account for the required flow on the basis of the theory presented in reference 7.

The significance of this duplex texture might be explained on the basis of experiments conducted in 1947 at Hammond Laboratory by Dr. R. E. Swift at the request of Professor C. H. Mathewson. The theory of stable textures described in reference 7 indicates that if a single crystal is deformed in the texture orientation, deformation will occur without changing this orientation. A torsion specimen was prepared from a single crystal of  $\alpha$  brass with an octahedral plane perpendicular to the torsion axis (111 direction parallel to the longitudinal direction in accordance with the first orientation listed above) and the specimen was given a shear strain of 1.68 in torsion. Unfortunately, here too, the provision for free torsion did not function and the specimen was also subjected to axial compression. The appearance of slip lines on the surface (Fig. 10) indicated that most of the deformation occurred by shear on the octahedral plane perpendicular to the torsion axis leaving the 111 direction essentially parallel to the longitudinal direction and substantiating the suggestion that this is the stable end orientation or texture for the torsion of face-centered cubic metals. This orientation is the same as the wire texture with a random range of orientations from 110 to 112 normal to the stress axis. In addition to these slip lines there were several deformation bands emanating from the grip ends and extending in a slow helix toward the center of the specimen (also shown in Fig. 10). In these deformation bands the slip lines were about 50° from those in the

matrix within 5° of where they should be for a (110) [001] orientation. It was my opinion that these deformation bands were the result of the stress complexity caused by the lack of free torsion or axial compression component, and that they would not have been there under pure torsion. There is the suggestion of the start of such a band in the upper right corner of the left micrograph of Dr. Backofen's Fig. 8.

It is my suggestion, therefore, that the texture for the pure torsional deformation of face-centered cubic metals is the same as the wire texture, namely 111 direction parallel to the torsion axis and a random range of orientations from 110 to 112 normal to it; and that lack of free torsion or the compression component in the torsion axis causes deformation bands to form of the orientation (110) [001].

**W. A. Backofen** (author's reply)—Dr. Hibbard suggests that the interpretation of the pole figures is not self-consistent because all of the octahedral poles associated with an ideal orientation do not fall in equally dense areas. This is certainly a significant comment, but it seems that it might be extended to other comparably accurate pole figures describing some of the more common cold-working textures. Fig. 11 is a (111) pole figure of cold-rolled copper which was constructed with the technique developed by Norton<sup>12</sup> and discussed in connection with Fig. 6 of the paper. The orientations included in this figure, while they do not position octahedral poles in equally dense areas, constitute the accepted description of the texture.

Dr. Hibbard's interpretation of the pole figures is particularly attractive because of its simplicity. But the writer avoided choosing the [111] wire texture with rotational symmetry about the torsion axis, for if this were developed it would seem that any direction from [110] to [112] in a (111) plane might act as a slip direction.

A slip direction could be expected to coincide with the transverse direction of maximum shear-stress, but it should be unnecessary for active slip planes to be oriented only perpendicularly to the torsion axis as the [111] wire texture would imply. It should be possible to rotate a slip plane originally perpendicular to the torsion axis about the active [110] slip direction without creating an unstable texture. By the rotation, the overall texture is broadened and the (111) [112] and (110) [001] orientations can be derived from the (112) [111]. It is not easy to rationalize the ideal texture (112) [131], which can be obtained very nearly from the (111) [112] by a 20° rotation about a [110] direc-

Fig. 11—(111) pole figure of OFHC copper reduced 95.5 pct in thickness by cold rolling.

Ideal orientations: solid square—(110) [112]; solid triangle—(112) [111].

tion lying in the plane of Fig. 7 and inclined 30° from the longitudinal direction. It may be that the contribution of this orientation to the description of the torsion texture is not important enough to warrant its use.

The [100] pole distribution was examined by means of a (100) pole figure and also by measurements of the intensity of reflection from (200) planes parallel to the flat surface of disk-shaped specimens removed from some torsion bars. These specimens were prepared so that their flat surfaces were perpendicular to the axes of the bars. It could be concluded from the information obtained in the two ways that there were some grains oriented with their [100] poles parallel to the longitudinal or torsion axis.

It is very interesting to learn that the deformation bands in the twisted single crystal described by Dr. Hibbard are of the orientation (110) [001]. These undoubtedly contribute to the overall texture. However, the pole figure of Fig. 4 was constructed from a specimen that was reasonably free from axial compression during twisting, and it is not different from the others.

This suggests that the (110) [001] part of the texture cannot be attributed entirely to deformation bands caused by the restricted torsion. Since this work was published, the axial compressive stress resulting from restricted torsion has been measured. For copper specimens used in this work, the stress rises gradually to a maximum of about 2000 psi, which is 8 pct of the corresponding shear-stress at a shear-strain of 2. It then decreases rapidly as the shear-strain increases. Thus the constraint is relatively small and again it does not seem that it is entirely responsible for the pronounced (110) [001] component of the texture.

Additional work on the torsion texture in polycrystalline  $\alpha$  brass has just been completed, but, unfortunately, the pole figures have not yet been prepared for publication. It is interesting to find that the (110) [001] orientation is a necessary, although minor, component of the texture. However, the [111] wire texture does not appear to be an adequate description of the balance of the texture.

## Effect of Ferrite Grain Structure Upon Impact Properties of 0.80 Pct Carbon Spheroidite

by M. Baeyertz, W. F. Craig, Jr., and E. S. Bumps

DISCUSSION, J. R. Low presiding

**R. M. Fisher and J. F. Boyce** (U. S. Steel Co., Kearny, N. J.)—In recent determinations of ferrite grain size in specimens of AISI-SAE 1060, deoxidized with 0, ½, 1, and 2 lb of Al per ton we found, in agreement with the authors of this excellent paper, that ferrite grain size established by tempering martensite is apparently independent of prior austenite grain size over a considerable range. We felt that others might be interested in our experiences with martensite tempered for shorter times, in which the spheroids were much smaller and much more closely grouped than those in the authors' specimens.

We found it difficult to estimate reliably ferrite grain

size with the optical microscope in specimens quenched from 1650°F, tempered for 1 hr at 1250°F, and etched with nital of various concentrations up to 5 pct. A typical micrograph of an aluminum-free specimen after this treatment is shown in Fig. 21a. Austenite grain size was ASTM No. 3 in this steel and No. 7 in those containing aluminum.

It was hoped that the X-ray diffraction technique described by Clark<sup>6</sup> would permit accurate measurement of ferrite grain size. However, continuous rings rather than individual spots were formed, which indicated merely that the ferrite grains were finer than ASTM No. 11.

Finally we resorted to the electron microscope and found that by etching these specimens in 2 pct aqueous ammonium persulphate solution for 10 sec, followed by 3 pct nital for 5 sec, we were able to observe ferrite grain size and structure. Collodion replicas, shadowed with uranium, were made of all four specimens. By counting grains in micrographs representing six randomly located areas for each specimen, we found the ferrite grain size of all specimens to be ASTM No. 15, regardless of prior austenite grain size or amount of aluminum addition. A portion of a typical electron micrograph of the replica from the aluminum-free specimen is shown in Fig. 21b. It should be noted that the etchant used shows the ferrite grains primarily because of differences in appearance of the surface of adjacent grains rather than by outlining grain boundaries.

<sup>6</sup>G. L. Clark: *Applied X-rays*, p. 504, 3rd Edition (1940) New York. McGraw-Hill Book Co.

Fig. 21a (left) — Tempered martensite, 1 hr at 1250°F. 5 pct nital etch. X2000.

Fig. 21b—Tempered martensite, 1 hr at 1250°F. Ammonium persulphate and nital etch. X9000.

Fig. 21c—Tempered martensite, 19 hr at 1250°F. 5 pct nital etch. X2000.

Fig. 21d—Tempered martensite, 19 hr at 1250°F. Ammonium persulphate and nital etch. X7000.

To investigate whether ferrite grain boundary delineation would be improved by longer tempering, the aluminum-free specimen was heated an additional 18 hr at 1250°F (Figs. 21c and d). Ferrite grain size was again determined by counting the number of grains in the known area of electron micrographs and was found to be ASTM No. 13.5, a five fold increase in volume.

The grains in the electron micrograph (Fig. 21d) appear more equiaxed than those in the optical micrograph (Fig. 21c). This seems to indicate that some of the elongated grains, observed with the optical microscope after etching with nital, consist of more than one equiaxed grain, but that nital failed to outline all boundaries adequately.

It was found that altogether 5 pct nital was not as satisfactory with the electron microscope as ammonium persulphate plus nital, ammonium persulphate plus nital was not as satisfactory as 5 pct nital when etching for the optical microscope.

We conclude that ferrite grain size may be measured by using the electron microscope and an ammonium persulphate plus nital etch, when it is difficult to outline grain boundaries satisfactorily for the optical microscope.

**M. Baeyeritz** (authors' reply)—The authors are grateful for the added information on ferrite grain structure presented by Messrs. Fisher and Boyce. When the ef-

fect of composition on ferrite grain growth as well as the influences of temperature and period at temperature are taken into account, the evidence in the optical and electron micrographs of the discussers seems to be in agreement with the optical observations of the authors. The ferrite grains in Figs. 21a and b are elongated and of the shape that might be anticipated from a martensite plate structure, but as stated in the discussion, considerable equiaxing and some growth of the ferrite grains was observed after treatment for 19 hr at 1250°F. With the 0.80 pct C-1 pct Ni steel used by the authors, the spheroidization treatment of 54 hr at 1150°F caused but very slight ferrite grain growth, so that the ferrite grain structure after this treatment was essentially the same as that observed with shorter periods of spheroidization at the same temperature. The difference in the rate of ferrite grain growth in the discussers' AISI-SAE 1060 steel and the authors' 0.80 pct C-1 pct Ni steel is ascribed to the differences in composition and spheroidization temperature used in the two cases.

We agree that electron microscopy is a useful tool for study of ferrite grain structures when used with the technique applied in the discussion. Because of the smaller field represented by any one electron micrograph, care must be taken to compare larger fields by light microscopy.

## Effect of Alloying Elements on True-Stress True-Strain Flow Curves of Pearlitic Steel

by R. Raring, J. A. Rinebolt, and W. J. Harris, Jr.

### DISCUSSION, J. R. Low presiding

**G. W. Geil** (National Bureau of Standards, Washington, D. C.)—The authors state that the degree of accuracy realized in the experimental determination of  $\sigma_f$  is likely rather low. This inaccuracy is attributed to the difficulty in reading the load of the tension machine at the instant of fracture of the test bars. I believe there is another factor which may have added considerably to the inaccuracy in the determination of  $\sigma_f$ , namely, the determination of  $\delta_f$ . Fracture of a cylindrical tensile specimen of a ductile metal tested in tension at room temperature is generally initiated at the axis and rapidly propagates radially to the periphery of the necked section. During the propagation of the fracture, the metal at the rim of the minimum cross-section extends longitudinally and contracts radially. Thus values of  $\delta_f$ , based on diameter measurements

Fig. 13—True stress-strain curve for a specimen of 0.3 pct C steel in the condition as-quenched from 1575°F and tempered 1 hr at 1000°F and tested in tension at 80°F.

M—values at maximum load. A—values based on diameter measurement at initial fracture. B—values based on diameter measurement after fracture.

Table V. Extent to Which Terminal Points Lay Above (+) or Below (—) Flow Curve

| Steel | Deviation, psi | Steel | Deviation, psi |

| P3    | 0              | V2    | − 500          |
| P4    | −4000          | V3    | + 500          |
|       |                | V4    | −1500          |

made after complete fracture of the specimens do not necessarily represent the strain at the initial fracture.<sup>11</sup> Data obtained at the National Bureau of Standards with a 0.3 pct C steel in the condition as-quenched from 1575°F and tempered at 1000°F for 1 hr and tested in tension at room temperature indicated a considerable "rim effect" and as shown in Fig. 13, resulted in an apparent increase in  $\delta_f$  from 0.90 to 0.98. As the fracture strain of this steel is approximately equal to those of the steels reported by the authors, it seems probable that a similar "rim effect" may have added to the inaccuracies in the reported values of  $\delta_f$  and accompanying values of  $E_f$ .

**R. Raring** (authors' reply)—The authors are grateful to Mr. Geil for having called attention to a possible source of uncertainty in the determination of fracture stress, and they are in agreement with the principles upon which his discussion is based.

<sup>11</sup> D. J. McAdam, Jr., G. W. Geil, and R. W. Mebs: *Trans. AIME* (1947) 172, p. 323; *METALS TECHNOLOGY* (August 1947).

However, it is considered that the "rim effect" in the majority of the pearlitic steels used in the investigation under discussion was negligible, and certainly less than in the quenched and tempered steel cited by Mr. Geil. This consideration is based on the fact that terminal points of the flow curves did not consistently lie above the straight line portion of the curve, as does point B in Fig. 13. It would be expected that if a marked "rim effect" occurred, the terminal points calculated from

the strain after fracture and the load at the beginning of fracture would lie above the straight line.

In Table V, the extents to which the terminal points were removed from the straight line are listed, and it can be seen that more were low (17) than were high (14), while 10 points were on the curve. Point B of Fig. 13 is approximately 15,000 psi above the extension of the curve. Thus only steels Mn 4, Cr 2, Cr 3, and Ni 4 show a marked upward deviation from the flow curve.

## Transitions in Chromium

by M. E. Fine, E. S. Greiner, and W. C. Ellis

### DISCUSSION, C. S. Barrett presiding

**C. H. Samans and W. R. Ham** (Chicago, Ill., and Dixfield, Maine, respectively)—For several years we have been studying transitions of this basic type in metals, alloys, glasses, etc. Usually, however, they are not so clearly marked as those which the authors have found, and hence are much more difficult to determine accurately. Since our studies indicate that most of them occur virtually unchanged (as far as temperature is concerned) regardless of the form in which the element appears, we believe that they are a characteristic of the atom.

Specifically, we believe that there is an additional rotational degree of freedom possessed by the nucleus which has not been considered heretofore. This nuclear rotation is made up of several components, each related to the several quantum shells of electrons. In chromium there are four of these shells and hence four separate series of characteristic transition temperatures. The lowest temperature at which any transition occurs, based on the present state of our computations, is 125°K, 4° higher than the authors' value of 121°K. A convergence of this series, we believe, shows up at the higher temperature of 2085°K, surprisingly close to the transformation temperature of 2103°K recently announced by N. J. Grant of M.I.T. for a body-centered to face-centered transformation in chromium.

Likewise, our computations indicate a temperature of 311°K for the second transition temperature, reported by the authors as 310°K. A convergence of this series, we believe, shows up at a higher temperature as the melting point at 2163°K.

Although our work on these series must, in a sense, still be regarded as empirical, since we do not understand fully as yet just what the series mean, it is based on a reasonably firm picture. The individual constants, from which the various series are computed for each element, comes directly from the X-ray K absorption limit. Furthermore, the same basic method has accounted for transformation and melting temperatures in about 50 of the chemical elements, which is all we have tried thus far. In many cases the only known transformation is the melting point, but in others the occurrence of transformations or other transitions, equally as well marked as those of the authors, has been pointed out by others. These observations have assisted us greatly. Consequently we were very pleased to see the authors' excellent work in finding these two transitions in chromium. With these confirming data, our picture of this element is clarified considerably, so we expect that at least some of our work can be published in the near future.

**R. C. Ruder** (E. I. du Pont de Nemours & Co., Wilmington, Del.)—The authors' interpretation of these transitions in terms of 3d to 4s electronic structure transitions is most interesting. It would be interesting to have additional experimental evidence of such transitions from the temperature dependence of the Hall coefficient in the neighborhood of the property changes discussed in this paper. Simple theory<sup>16</sup> suggests the Hall coefficient as a measure of the free electron (or s

electron) concentration per unit volume. It has been shown that for paramagnetic<sup>16</sup> and ferromagnetic<sup>17</sup> metals the simple theory is in fact too simple. However, the existence of a discontinuity in the Hall coefficient would provide information which should aid both in our understanding of these transitions and the significance of the Hall coefficient in these metals. It was rather surprising that no significant paramagnetic effects were observed. In this connection the recent work of McGuire and Kriessman<sup>18</sup> is cited. They measured the magnetic susceptibility of chromium from 20° to 1460°C. They also observed no large change in the susceptibility although there might be a change in slope in the vicinity of the 40°C transition.

The existence of these 3d to 4s electronic transitions has been discussed in connection with the paramagnetic susceptibility behavior of nickel and nickel alloys.<sup>19-21</sup> Assuming a correspondence principle between classical and quantum mechanical paramagnetic theory and using classical theory to calculate the effective Bohr magneton number from the Curie constant for substances obeying the Curie-Weiss law,<sup>22</sup> it is found that the effective magneton number is a function of temperature. The process of calculation involves the inverse of the differential of the  $1/x_A$  vs. temperature curve so that good and numerous data are necessary to obtain significant results. The data of Fallot<sup>23</sup> show a discontinuous increase of about 12 pct in the effective magneton number between 850° and 900°C, followed by a continuous increase up to the melting point. The data of Sucksmith and Pearce<sup>24</sup> show a possible 8 pct increase. The older data of Terry<sup>25</sup> and Weiss and Foex<sup>26</sup> show a continuous increase. It is possible that small amounts of impurity atoms change these electronic transitions significantly. Fallot's<sup>23</sup> data on a nickel alloy with 4.5 atomic pct Fe indicate that the discontinuity occurs around 1300°C.

Systematic investigation of the transition metals for transitions of this nature should provide information which would be very valuable for our understanding of these metals.

The absence of antiferromagnetic structures in chromium has been shown by Shull<sup>27</sup> using neutron diffraction techniques.

**M. E. Fine, E. S. Greiner, and W. C. Ellis** (authors' reply)—The remarks by Drs. Samans and Ham are certainly very interesting, in particular those pertaining to the close agreement between the theoretically calculated values for transition temperatures in chromium and the experimental values reported by a number of investigators. This is a remarkable achievement and we shall look forward to a more detailed presentation of the method followed in their calculations.

We do not believe that the transition in pure chromium near 40°C remains temperature invariant with alloying, as was reported by Samans and Ham for a number of the substances that they studied. We have not done any work with alloys but base our belief on the results of earlier studies in which less pure chromium was included and considerably lower transition temperatures were observed. The transition tempera-

ture, it would be expected, would be changed by solid solution alloying through modification of the electron distribution in the chromium atom by the neighboring solute atoms. The transition is still primarily a property of the chromium atom.

We appreciate Dr. Ruder's discussion of the results of susceptibility measurements on chromium which were not available to the authors at the time the paper was presented. It is gratifying that these measurements support our conclusion that the transition near 40°C is not loss of antiferromagnetism. This seems to be confirmed by the neutron diffraction measurements subsequently reported by Shull. We agree that precise measurements of susceptibility and Hall coefficient would be of great value for filling in some of the details of this transition.

## Lattice Parameters of Magnesium Alloys

by Robert S. Busk

DISCUSSION, M. Hansen presiding

**William Wilson, Jr.** (*Armour Research Foundation, Chicago*)—In his treatment of the relatively soluble group of alloying elements, the author has calculated the regression coefficients, and found that the  $c/a$  coefficients for gallium, mercury, and zinc are not significantly different from zero. However, the Student  $t$ -test may fail to indicate a significant difference, even if one exists, when insufficient data are tested. The same binary alloys are also those for which the minimum number of observations are available. For these cases, at least, it would be desirable to calculate the fiducial limits of this coefficient. The author's data for magnesium, showing the individual results for each of the five samples, and a knowledge of his weighting procedure in finding these regression coefficients, would be required to calculate the fiducial limits.

Although the work of the previous investigators, reviewed by Raynor,<sup>15</sup> indicates a minimum in the  $c$ -spacing vs. atomic pct curves for indium and thallium, and an inflection point in the curves for aluminum and gallium, the author's treatment precludes finding these features of the curves. If a suitable equation for these previous investigations were also tested against the data, then the standard errors of the two might indicate

the more exact treatment.

At the first reading, it may appear that the author has tested all of the lattice parameters of the relatively insoluble group with the assumption that the populations were infinite. Actually, in a novel way, the author has corrected the  $t$ -values in a way to make this a significant basis for comparison. I wonder if, in calculating the standard errors, the degrees of freedom were considered instead of the " $N$ " defined as the "number of data points."

**R. S. Busk** (author's reply)—The minimum in the  $c_0$  parameter is obtained by combining the data for the  $c/a$  ratio and the  $a_0$  parameter. The  $c/a$  ratio was considered more fundamental and was therefore studied more exactly. In those cases having a minimum in the  $c_0$  parameter, the equation does not reduce to the value of pure magnesium at zero concentration. It is therefore evident from this alone that there is a break of some type in the curve. If the  $a_0$  parameter is decreasing while the  $c/a$  remains constant, then the  $c_0$  must also decrease.

The standard errors were calculated by using  $N$  rather than  $N-F$ .

## Intergranular Energy of Iron and Some Iron Alloys

by Lawrence H. Van Vlack

DISCUSSION, H. L. Burghoff presiding

**C. S. Smith** (*University of Chicago, Chicago*)—The author is to be congratulated on his valuable contribution to the extremely meager absolute data on interface energies in metallic systems.

It is interesting to note that the ratio between  $\alpha$  and  $\gamma$  iron boundary energies is approximately the same in the quaternary alloy with silicon, carbon, and sulphur as in the binary Cu-Fe alloy. A value for the copper grain boundary energy can be obtained from the author's data, Tables IV and VI, by utilizing the energy ratios of the following pairs of interfaces: copper-sulphide/copper, copper  $\gamma$  iron,  $\gamma$  iron/ $\gamma$  iron,  $\gamma$  iron/

copper, and copper/copper. This gives a value of 595 erg per sq cm for the free energy of the copper grain boundary. Despite this circuitous route and the assumption that the  $\gamma$  iron boundary is identical in alloys with and without sulphur and does not change between 1105° and 1000°C, this figure is in remarkably close agreement with other values of the copper boundary energy, obtained by equilibration against lead and against the free copper surface. It therefore appears either that impurities do not greatly affect the grain boundary energies or that boundaries in even nominally pure metals are already sufficiently contaminated so that further change has little effect.

# Formation of Annealing Twins

by J. E. Burke

DISCUSSION, H. L. Burghoff presiding

**R. G. Treuting** (*Bell Telephone Laboratories, Murray Hill, N. J.*)—A growth-accident hypothesis of annealing twin formation raises a question which may deserve clarification. In heavily anneal-twinned material such as  $\alpha$  brass, parallel-sided twin bands are by far the predominant form observed. This requires for the present theory that following one growth accident to generate a twin orientation, the most probable subsequent growth accident be on an octahedral plane of the same set, i.e., parallel to the existent composition plane. The implication is twofold: first, that the direction of grain growth remains the same for original and twinned components; and second, that this still advancing octahedral plane (now rotated about its own pole by twinning) remains the most likely to meet an aggregation of atoms suitably disposed for another accident.

The first condition seems to impose little difficulty. The evidence advanced by Dr. Burke indeed supports the choice of  $\langle 111 \rangle$  as a favored growth direction, and this would not be altered by the twin accident. Yet there are three other  $\langle 111 \rangle$  symmetrically arranged about that operative in an accident. Although subsequent twinning does occur about one of these alternative poles from time to time, one particular set of octahedral planes is more often consistently favored, as shown by successive parallel twin bands. After a twinning accident, the operative set of planes should have by far the largest area of the four in the twinned material. It may then be that its probability of encountering an orientation suitable to further twinning is correspondingly larger even though growth may be proceeding at the same rate in all four  $\langle 111 \rangle$  directions. I do not know that this explanation is adequate and would appreciate any comments from the author.

I should like to offer two tentative suggestions with respect to points Dr. Burke considers unresolved:

1—He has already noted grain boundaries as a discontinuity likely to cause twinning during grain growth. The frequency with which a growing grain meets a new orientation that may permit twinning is then a function of the then prevailing grain size. The relative constancy of twin density (twins per grain) throughout grain growth may be related to this. That is, the larger the grain size, the less often a twin accident is likely to occur.

2—It is possible that when a growing grain meets an orientation nearly suitable for a twin accident, whether or not this occurs may be controlled by the states (e.g., the surface energies) of the incident planes. The intensity of twinning may be related in this manner to the presence of solute atoms and so vary among alloys. This, to be sure, is not a crystallographic argument and perhaps does not lie within the intended scope of Dr. Burke's paper.

**W. G. Burgers** (*Technische Hogeschool, Delft, Netherlands*)—The subject of Dr. Burke's highly interesting paper is one which has been occupying me (and probably other metallographers) considerably during the last years. The two main possibilities, brought forward in the paper to explain the formation of annealing twins, viz: 1—the mechanical nucleation hypothesis, and 2—the growth fault hypothesis, have been discussed.<sup>13, 14</sup> In these papers direct experimental evidence was given by means of the "electron emission loupe" for the fact, mentioned in Dr. Burke's paper, that the width of twin bands bounded by parallel sides remains unchanged. In this investigation by means of the electron emission image a cinematographic record was obtained of the growth, by "exaggerated grain growth" ("secondary recrystallization") of nickel-iron foil, which shows clearly that twin lamellae grow

parallel to their straight boundaries (cf. Fig. 8). This fact, which is also clear from Dr. Burke's Fig. 4, seems therefore well established.

The idea that the condition for twins to grow wider is to have a grain boundary as one side, seems to me very stimulating, also the evidence that twins usually form at or near the corner of grains. In this connection the explanation brought forward in a recent note by Fullman<sup>15</sup> is of the greatest interest.

The suggestion given there, due to J. C. Fisher, "that an annealing twin forms in the corner of a growing grain when the orientation relationships between the twin and the grain's neighbor lead to a smaller total interfacial energy than do the orientation relationships between the grain itself and its neighbors," makes it in principle understandable: 1—that twin formation is of necessity related to "lattice faults" (grain boundaries included), which explains why the same metal can "crystallize" without considerable twinning (for example when crystallizing from the melt), 2—that the frequency of twinning depends to a large extent on the "texture" of the matrix in which recrystallization or grain growth takes place, and 3—that different cubic face-centered metals, like copper and aluminum, may differ so much in their twinning frequency as a consequence of a different degree of anisotropy of surface grain boundary energy.

With regard to the above suggestions, I should like to point out that for some time I thought that a somewhat different mechanism, to some extent related to the growth fault hypothesis, might account for them. Although I feel inclined at present to consider a mechanism as proposed by Fisher to be more probable,\* yet I cannot give up this idea completely.

The starting point for my considerations<sup>16</sup> was the formation, observed when recrystallizing fine grained aluminum by "primary recrystallization," of "pointed grains" (like B in Fig. 9), the lattice of which appeared to be in exact spinel-twin position (within at least 1

\* I must confess that, although grasping the general idea underlying Dr. Fullman's short note, I find difficulty in deducing from the figure given how the atomic processes leading to the twin formation should be visualized.

Fig. 8—Electron optical observation of the formation of twin lamellae of constant width during growth of a large crystal in nickel-iron foil by "secondary recrystallization" (from references 13 and 14). X25.

Fig. 9—"Pointed" twins (B) formed by "stimulation" by crystal A. Natural size. Area reduced approximately 40 pct for reproduction.

min of arc<sup>17</sup>) with regard to the lattice of the "surrounding crystal" (A in Fig. 9).

It was shown that the occurrence of such point-shaped crystals can be understood on the assumption that growth of such a "stimulated" crystal starts at the moment that an already growing "stimulating" crystal comes into contact with its nucleus, which was supposed to be a lattice region of the original matrix. In connection with the observed precise twin relationship existing between both crystals, it was thought possible that, on such encounter, "elimination" of a set of dislocations at the plane of contact, by mutual annihilation of dislocations of opposite "sign" (opposite "sense" in case of screw-dislocations) might cause a release of strain energy in the contacted lattice domain, which thus might be transformed into an active nucleus itself. Of course the frequency of such an event would depend largely on the texture of the matrix, as it would be controlled by the chance of a growing crystal to meet a lattice region in "precise" twin position, which it could stimulate to growth. In agreement herewith it was found that even in the same metal, in this case aluminum, the frequency of such twin formation depended very much on the texture of the matrix and varied from case to case.

On the basis of these experimental facts it was thought possible that the frequent twinning in metals like copper, nickel-iron, etc. might be due to the circumstance that the new crystals often develop in a matrix with a fairly pronounced texture, for example the cubic texture in the case of secondary recrystallization of annealed rolled foil. Moreover, as we know from various investigations,<sup>7</sup> these new crystals occupy positions which are related to the matrix texture by rotations about an axis normal to an octahedral plane. Although the amount of rotation, according to most investigators, differs from that observed for exact twinning, it must be kept in mind that these data are deduced by comparing the positions of the new crystals with the "centers" of the pole figures of the matrix. As these latter do generally show a considerable degree of scattering, it seems, a priori, not impossible that the crystals in the course of their growth repeatedly met individual grains of the matrix, which, with regard to them, occupy exact twin positions. In such cases, according to the suggestion given here, stimulation could take place, thus causing a lattice element of the disappearing texture to grow in exact twin position with regard to the already growing crystal, and so forming an "annealing twin." It is evident, however, that this mechanism, when occurring in a pronounced texture, would lead principally to a family of twins corresponding to the matrix-texture; whereas, as Dr. Burke points out, frequently examples of grains with several families of twins are observed.

In annealed rolled aluminum, where, according to Beck and coworkers,<sup>20</sup> similar orientation relationships between matrix and new crystals hold, the fine grained texture is generally less pronounced than in copper or nickel-iron. This, I thought, might explain, why, in aluminum, the "twins" have in general curved bound-

aries (cf. Fig. 9), as contrasted to copper, etc., where straight edges are generally formed. In fact, the "curved" twins in aluminum grow in matrices with an only slightly pronounced, or even nearly random, texture, so that the boundary-orientation relationship between growing grain and matrix changes from grain to grain; whereas in copper, etc., the texture is generally far more pronounced, possessing for example the "cube-texture," so that growth conditions will remain more constant over longer distances. I must say, however, that I feel not quite clear with regard to this point. In any case, it is a fact that, on recrystallizing a deformed aluminum matrix with a pronounced texture, obtained by rolling a single crystal, "twins" with straight edges are also formed;<sup>21</sup> whereas, on the other hand, the large copper crystals obtained by Cook and Macquarie<sup>22</sup> in cross-rolled copper by "abnormal grain growth" (which has a more random texture than foil rolled in one direction only) show many curved boundaries.

In order to have a direct test that the frequency of twin formation depends upon the orientation relation between growing grain and matrix texture, use might be made of the method of growing a crystal "round the corner," as applied by Tiedema<sup>23</sup> for the preparation of large aluminum crystals with a definite orientation with regard to the surface directions of the test-piece (which method is closely analogous to that applied by Dunn<sup>24</sup> and coworkers for preparing iron-silicon crystals with definite orientations): if in a fine grained matrix with a fairly sharp texture, we start growth of a large crystal at one end by pulling it partly through a heating zone, then bend the not yet recrystallized part and proceed with the growth of the large crystal "round the corner" by now passing the whole test-piece through the heating zone, then we may expect that the frequency of twinning is different at both sides of the "bent," as the relative position of growing grain and to-be-consumed matrix is different before and after passing the "bent." We intend to carry out this experiment. Of course, in case the above expectation comes true, this experimental fact is not exclusively in favor of the "stimulation" theory; it might also be expected on the basis of the views given in Dr. Burke's and Dr. Fullman's papers.

**J. E. Burke** (author's reply)—I should like to thank Professor Burgers and Dr. Treuting for their kind and stimulating discussion of my paper. In particular, I should like to thank Professor Burgers for calling attention to his earlier discussion of these two mechanisms and to his evidence that parallel-sided twin bands do not grow in width.

The stimulation mechanism for the formation of twins which Professor Burgers has proposed is very ingenious. It might be pointed out that it cannot operate to form twins during grain growth since the strained fragments or nuclei necessary for the mechanism are not present.

On the other hand, in a deformed metal, either the stimulation or growth accident mechanism could operate. An experimental method of deciding between these mechanisms would be desirable. Professor Burgers suggests an experiment in which the frequency of twinning is observed in a grain as its orientation and growth direction with respect to a textured matrix is observed. Unfortunately, as Professor Burgers points out, a change in twinning frequency with texture could be explained by either mechanism. In fact, some evidence that the direction of growth influences the intensity of twinning was presented in this paper and used to support the growth accident hypothesis. Nevertheless, the results of the experiment will be highly interesting and will certainly help describe the conditions necessary for the formation of twins in greater detail.

I should like to suggest another experiment which might possibly allow a decision to be made between the two possible mechanisms in the formation of the pear shaped "stimulation" grains Professor Burgers shows in Fig. 8. The stimulation hypothesis requires

that the stimulated grain and its stimulator or parent have a (111) slip plane in common, and this (111) plane will, of course, be the twinning plane. In order for the dislocations to move in a proper direction, this (111) plane must be approximately normal to the interface between the two grains at the moment of stimulation. Thus it might be expected that this (111) plane would contain a line which would approximately bisect the angle of the stimulated grains.

On the other hand, if the "stimulated" grain were to have been formed by the growth fault mechanism, the twinning plane should be approximately perpendicular to the line bisecting the apex of the "stimulated" grain, that is, the (111) twinning plane must coincide with the initial interface between the "stimulated" grain and its parent.

The obvious experiment is to determine the position of the twinning plane for a number of cases of stimulation in aluminum. If its position is reproducible with respect to the apex of the stimulated grain it should be possible to draw a conclusion as to mechanism.

If it develops that the position of the twinning plane between the parent and stimulated grain is more or less random, then, unfortunately, no decision will be possible. This could result from the fragment having been partially surrounded before stimulation occurred. It could equally well have resulted from a growth fault occurring on the side of a projection on the parent grain. These should, however, be more or less random, so that if the position of the common (111) plane in a number of stimulated grains are determined, no false conclusion should be drawn.

In reply to Dr. Treuting's first question, I would agree with his explanation. Where a twinning accident occurs it indicates that a grain was growing approximately normal to that (111) twinning plane. Since the twin is in a symmetrical orientation it will probably continue to grow in the same direction, and, as Dr. Treuting points out, the greater part of its advancing front will approximate the (111) twinning plane so that it will be most probable for the next twin to form on that (111) plane and reproduce the original orientation. In further support of this explanation advanced by Dr. Treuting, I can cite Fig. 5 of the paper. Here, on the right hand side, the grain had grown a great deal before any twinning accident occurred, so the condition that the advancing front of the grain is all approximately parallel to a single (111) plane was not

fulfilled. Here, twins on two other octahedral planes formed.

To some extent I think the apparent preponderance of parallel-sided twin bands is an optical illusion, however. Many grains have more than one family of twins, and this definitely means that during growth, a grain which formed a twin on one plane at one place formed a twin on a different plane some place else.

As regards Dr. Treuting's suggestion on the constancy of number of twins, it explains the increase in width to twin bands as the grain size increases, but it still seems the number of twins per grain would be expected to increase, because presumably all those formed when the grain size was small would still be there.

It seems very probable that the variation in intensity of twinning from alloy to alloy is controlled by the surface energy of interfaces. Essentially the same argument as Dr. Treuting uses, and supporting evidence for it, has been presented very recently by R. L. Fullman.

## Atomic Relationships in the Cubic Twinned State

by W. C. Ellis and R. G. Treuting

DISCUSSION, H. L. Burghoff presiding

D. Whittham, M. Moufflard, and P. Lacombe (*British Council Research Fellow, Laboratoire du Professor Chaudron, Vitry-sur-Seine; Ingenieur de Recherches, Laboratoire de Vitry; and Maître de Recherches, Laboratoire de Vitry, Professeur Adjoint de Metallurgie, Ecole des Mines, Paris*)—The authors' work is of great interest in bringing out the geometrical relations existing between twinned lattices, and for the notion of a coincidence superlattice developed from this.

We should like to point out that a similar idea was put forward by Friedel<sup>1</sup> in his book on the subject of lattice merohedrim "merihedrie réticulaire."—When two crystals A and B are twinned with respect to a mirror plane, there exists a common superlattice, "réseau période," which is independent of the contact surface between the two crystals. The volume V of this superlattice is a simple multiple of the volume v of the lattice of crystals A, or B, (Fig. 5). This "multiple

cell" is defined by the twin plane (pqr) and a row of atoms [hkl] normal to this plane, the base being taken as the smallest unit (two-dimensional) of this plane. Two cases must be considered. First when the multiple cell, as defined, has no atom site at its center nor at the center of its faces other than (pqr),

the twinning index is defined by  $\frac{V}{v}$ . In the second

case, when one of the two above conditions does not

apply, then the twinning index is  $\frac{V}{2v}$ .

A more intuitive definition of the twinning index would be the proportion of atoms of C<sub>2</sub> which would coincide with those of C<sub>1</sub> when the C<sub>2</sub> lattice is imagined to extend on the other side of the contact surface. In the case of cubic crystals, the twinning index

is given by the relation:

$$\Sigma = (p^2 + q^2 + r^2) \text{ if } \Sigma \text{ is odd.}$$

$$= \frac{p^2 + q^2 + r^2}{2} \text{ if } \Sigma \text{ is even.}$$

(p q r) being the mirror plane.

Thus for the face-centered cubic system with twinning on the octahedral plane (111),  $\Sigma = 3$ . Similarly for body-centered cubic twinning on (112), we have also  $\Sigma = 3$ . These results are confirmed by the atomic patterns given by the authors in which it is demonstrated that, parallel to the twinning plane, one plane in every three coincides (two in every six for the diamond lattice).

The concept of "multiple cell" developed by Friedel and analogous to the coincidence superlattice of Ellis and Treuting, though it explains the general stability of the twinned group, does not forecast the position of the boundary surface between the twins. To the metallurgist, such boundary surfaces present a rather exceptional interest in the study of boundary energy. Thus the authors bring out the fact that the (111) plane of contact for face-centered cubic twinning, and (112) for body-centered cubic twinning, corresponds with conditions of minimum distortion of the lattice, though in both cases the two lattices are symmetrical with respect to either a (111) or a (112) plane.

For our part, we have tried to extend this idea of minimum distortion in the case of boundaries between multiple twins, and the lateral interfaces noted by the author.

In an earlier paper, Ellis<sup>4</sup> presented an extremely interesting example of multiple twinning in a germanium ingot, and in the following we use a similar system of symbols. Thus if a crystal A has two first-order twins B<sub>1</sub> and B<sub>2</sub> on two different octahedral planes, then B<sub>1</sub> and B<sub>2</sub> are said to be second-order twins. Thus, we have shown that between B<sub>1</sub> and B<sub>2</sub> there exists necessarily a twin relation with mirror planes (221) and (114) and (114). Fig. 5 clearly shows this relation. In a general way, the Friedel index of a twin of order p can be determined and from it the Miller indices of possible mirror planes deduced. Thus:

| Order of Twinning | Friedel Index | Mirror Planes                                                    |
|-------------------|---------------|------------------------------------------------------------------|
| 1                 | 3             | (111) or (112) (equivalent)                                      |
| 2                 | 9             | (221) or (114) (equivalent)                                      |
| 3                 | 27            | (255) or (511) (first possibility)<br>(721) (second possibility) |

In their theoretical treatment of grain boundary energy as a function of boundary and grain orientation, Shockley and Read<sup>9</sup> have directed attention to the special interest of twinned lattices with the consequent possibility of realizing boundaries of low energy other than the twin plane (energy cusp boundaries). Such boundaries or planes of good atomic fit are the lateral twin interfaces given by the authors. The number of such possibilities is infinite but in practice the surfaces of interest are thought to be limited to planes of high atomic density. Stereographic projections for first, second, and third-order twinning enable the indices of planes which are parallel in the two lattices to be determined; and all such planes are possible lateral interfaces of the twin.

In the first place our attention was directed to the interfaces of second and third-order twins as it was believed that the particularly low energy of the (111) boundary would tend to suppress the appearance of other cusp boundaries in first-order twins. With this in mind, we attempted to interpret the crystal orientations in the micrograph of germanium given by Ellis.<sup>4</sup> The large crystal A (Fig. 6) has contacts only with twins B<sub>1</sub> and B<sub>2</sub> following the lettering, but we have assumed a third contact with B<sub>3</sub> at the top left hand

Fig. 5—Diagram showing first-order twinning between lattices A and B<sub>1</sub> (111), A and B<sub>2</sub> (111), and the resulting second-order twin B<sub>1</sub>B<sub>2</sub> with mirror planes (221) and (114).

The section shows the (110) plane parallel in all three crystals with the multiple cells of Friedel for AB<sub>2</sub> and for B<sub>1</sub>B<sub>2</sub>, in thick solid lines. The three lattices are shown by solid lines while the prolongation of a lattice is marked by dashed lines.

Fig. 6—Schematic drawing to show types of boundary contact between second-order twins.

B<sub>1</sub> and B<sub>2</sub> are first-order twins of A, and C<sub>1</sub> is a first-order twin of B<sub>1</sub>; B<sub>1</sub>B<sub>2</sub> and AC<sub>1</sub> are thus second-order twins.

Fig. 7—Stereographic projection to fix the orientation of crystal A in the micrograph of Ellis, from the trace of (111) twin planes between AB<sub>1</sub>, AB<sub>2</sub>, and AB<sub>3</sub>.

The (122) mirror plane of the second-order twin AC<sub>1</sub> is seen to lie on the normal to the boundary between A and C<sub>1</sub>. Solid triangle —(111) poles of crystal A. Solid square in triangle—(111) twin plane for B<sub>1</sub>C<sub>1</sub>.

Fig. 8—Multiple twinning in copper sheet specimen recrystallized after a small permanent extension.

$B_1$ ,  $B_2$ , and  $B_3$  are first-order twins of  $A$ , while  $C_1$  is a first-order twin of  $B_1$  (or third-order twin of  $B_2$ ). Note the point of convergence,  $F$ , of the four crystals,  $A$ ,  $B_1$ ,  $B_2$ , and  $C_1$ . X60

side of the photograph, where the similarity of tint and parallelism of boundaries  $A-B_2$  would appear to indicate another part of crystal  $A$ . Thus in the stereogram (Fig. 7), we have plotted the (111) poles of crystal  $A$  and indicated the three twin planes. It will be remarked immediately that the twin boundary between  $B_1$   $C_1$  becomes identifiable with the (111) pole of crystal  $B_1$ ; which encouraged us to believe that the construction used was sound. The crystals  $A$  and  $C_1$  are automatically second-order twins with two possible mirror planes (221) and (114). Finally the normal to the boundary  $A-C_1$  has been traced on the stereogram and is seen to pass through the pole of the mirror plane (221) suggesting that the composition plane for this second-order twin is the mirror plane with perfect coincidence of all atoms. We would be very interested to know if our construction is in agreement with the orientations determined by X-rays, and to know whether the boundaries shown have been examined in detail.

The large number of twins found in the germanium ingot has led the authors to suggest that the diamond cubic lattice is particularly favorable for this phenomenon. We should like to point out, however, that numerous twins have also been observed in aluminum, in certain cases of semicontinuous casting.<sup>10</sup> In addition, we have found that the formation of twins of different orders is also demonstrated by the recrystallized structures of face-centered cubic metals such as copper, aluminum, and stainless steel (18/8). One such ex-

ample is shown in Fig. 8, taken from a copper sheet specimen which had been elongated 1.5 pct and then annealed at 900°C to obtain large crystals, after the method of Carpenter and Tamura.<sup>12</sup> The large crystals so obtained are not immediately evident as they are almost always subdivided into a system of multiple twins. The size of the individual twins was too small for convenient examination by the Laue method, but the problem of determining orientations was considerably simplified by forming a thin sulphide film<sup>13</sup> on the surface. As all grains having a given crystal plane parallel to the surface develop the same interference color, we preferred examination in polarized light because only those grains of the same orientation (in three dimensions) are similarly colored (see Fig. 9). Evidently for a precise determination of orientation relationships it was necessary to choose grain groups in which at least one grain had accompanying twins showing the trace of three different (111) planes.

The stereogram of Fig. 10 has been constructed in this way making use of the (111) twin boundaries between  $AB_1$ ,  $AB_2$ ,  $AB_3$ . The orientation relationships may thus be represented:

$$\begin{array}{c} B_3 \rightarrow A - B_1 - C_1 \\ \downarrow \\ B_2 \end{array}$$

with boundary contacts between the second-order twins  $B_1$   $B_2$ , the third-order twins  $C_1$   $B_2$ , as well as the remaining first-order twins. The micrograph shows a number of phenomena which are typical in the sense that they occur frequently.

1—The boundary surfaces between twin crystals of the second and third order do not coincide with the possible mirror planes. Whenever the contact is not a plane one, at the magnification used, it is of course not possible to determine the crystal surfaces involved. A number of plane surfaces have nevertheless been observed of which we mention particularly the contact (111)<sub>A</sub> (115)<sub>B</sub>, because of its frequent occurrence and as evidence of a boundary mentioned specifically by the authors, to demonstrate the exact coincidence of atoms possible on a lateral interface though applying to only one third of the atoms, due to the difference in atomic density for the two planes.

2—The surface between first-order twins is in large part the (111) twin plane but a number of other planes of contact were observed. Thus a boundary which at low magnification was apparently curved was often found to consist of series of small steps at a much higher magnification. One such example taken from a twin in aluminum is shown in Fig. 11.

3—Finally, an example is shown of four boundaries meeting in a single point. As this point of convergence was conserved after several successive polishing op-

Fig. 9—Micrograph of copper carrying a thin sulphide film for recognition of grains of the same orientation by examination in polarized light between crossed nicols. X60.

Owing to the difficulty of reproducing colored photographs, Fig. 9 was replaced by two black and white photographs of the same grain group as seen in ordinary and polarized light. Difference in contrast is apparent but the wider variety of tints and color sensitivity cannot be appreciated.

erations, it is deduced that the four surfaces must meet in a row of atoms. Knowing that three of the four surfaces are in fact (111) twin planes, it becomes evident that the row of atoms corresponds to a [101] direction which is the zone axis to the three (111) planes. Such an arrangement can therefore only occur when the third-order twin between  $C_1B_2$  is of the type with mirror planes (511) — (255); and not for the alternative (721) twin.

As already noted, our observations were made on specimens which had been recrystallized and thoroughly annealed, suggesting that such structures are comparatively stable. That the boundary between first-order twins so often consists of a series of different plane junctions, which meet in an edge row of atoms, is an interesting confirmation of the theoretical forecast by Shockley and Read<sup>9</sup> that certain boundary positions produce cusps in their energy-orientation curve.

Without specifying any precise mechanism of twin formation, it seems nevertheless probable from the morphology of multiple twin groups that whereas first-order twins are generated directly from a primary crystal A, second and higher order twins are the

Fig. 10—Stereogram constructed from the traces of twin planes  $AB_1$ ,  $AB_2$ , and  $AB_3$  of Fig. 8.

Solid triangle—(111) poles of crystal A. Open circle in triangle—(111) twin plane of first-order twin  $B_1C_1$ . Solid circle—Mirror planes (114) and (221) of the second-order twin  $B_1B_2$ . Greek cross—Mirror planes (115) and (552) of the third-order twin  $C_1B_2$ . Solid square—direction [101] common to the four crystals, A,  $B_1B_2$ ,  $C_1$ .

incidental result of junction between two such twins  $B_1$  and  $B_2$ .

In the latter case, the junction surface may or may not have any special orientation as demonstrated by the scheme of Fig. 6. Whether such boundaries can move to some other position, representing lower energy, is not known but is now being studied. This question has already been studied in some detail by Dunn and coworkers<sup>14</sup> for the body-centered cubic system (iron-silicon).

**W. C. Ellis and R. G. Treuting** (authors' reply)—The discussion of Messrs. Whitman, Moufflard, and Lacombe is a valuable addition to the paper, particularly appreciated in that it offers experimental evidence in support of the thesis projected by the authors. We are also grateful to the discussers for making available in English so concise and illuminating a résumé of the earlier exposition of coincidence sites and multiple cell structure in twinned lattices by Friedel. This reference, we regret, was overlooked.

Professor Lacombe and his colleagues are entirely correct in their deductions of the correlations of twin relations and interface traces in the micrograph in an earlier paper<sup>4</sup> by one of the authors. X-ray evidence, not included in the earlier paper, attests to this concordance. The straight portion of the second-order junction trace, A- $C_1$ , is consistent with a {221} plane, one

Fig. 11—Boundary between twinned crystals of aluminum, apparently curved at small magnification, but resolved into a series of steps parallel to different crystal planes.

The boundary appears thick under the oblique illumination used because the twin plane lies almost parallel to the surface. X2000.

of the mirror planes of regions A and  $C_1$ . We had been discouraged from making a point of this, however, since the A- $C_1$  junction appears curved at low magnifications over a considerable portion of its extent. The curved portion conceivably may consist of distinct crystallographic segments to be revealed only by very careful surface preparation and examination at high magnification. This is an attractive possibility; but we have not yet made such examinations.

The discussers have added a welcome reference (reference 10) to the occurrence of twins in semicontinuously cast aluminum. We do not think that this seriously weakens our suggestion that the diamond cubic structure is particularly favorable for twinning, but rather strengthens it. The aluminum ingot referred to appears to be made up in the central portion of long parallel natural grains or crystals each of which is twinned. The slice from the germanium ingot, however, consists entirely of regions in multiple twin relationships. This multiple twin relationship has more recently been confirmed throughout an entire ingot and may quite confidently be presumed general.

In the course of following the interesting deductions of Professor Lacombe and his colleagues with respect

Fig. 12—Stereographic projection constructed from traces in Fig. 8 to illustrate types of coincidence at lateral twin boundaries.

to the twinned copper sheet of Fig. 8, we have reconstructed the stereographic representation of their Fig. 10 employing also normals to additional boundary traces as directly measured on the micrograph. It is evident that the rotations generating  $B_1$  and  $B_2$  from  $A$ , and  $C_1$  from  $B_1$ , can all be taken to be  $70^\circ 32'$  each about the common pole [101], which is the conserved line of intersection of four boundaries pointed out in discussion.

We first directed our attention to the boundary between the third-order twins  $B_2$ - $C_1$ , which appears fairly straight. We succeeded in ascertaining only that it coincides with neither the {115} nor the {525} mirror plane between these orientations in agreement with the findings of the discussers. This boundary could be a (111) plane of  $B_2$ , but seems to have no index pair low for both orientations.

On the other hand, the lateral boundaries between first-order twin pairs  $A$ - $B_2$  and  $B_1$ - $C_1$ , the loci of whose normals are shown in Fig. 12, are very closely consistent with, respectively, the planes (575) of  $A$  and (131) of  $B_2$ , and the planes (141) of  $B_1$  and (101) of  $C_1$ . Both these pairs, as well as the {111}::{115} type, lie in the common [101] zone, which thus seems to be experimentally indicated a favorable one for the occurrence of coherent lateral boundaries. The  $(575)_A::(131)_{B_2}$  is a lateral twin boundary also found in copper by Fullman<sup>15</sup> in his extensive examination of grain interfaces,

but this is the only pair of low-indexed planes consistent with any of the lateral twin boundaries observed by him.

The statement by the discussers that second and higher order interfaces are incidental junctures between directly generated first order and successive first orders is not to be contradicted by the evidence for copper here presented. The case for germanium may be different: here all orientations in the ingot seem interrelated through sequences of twinning. It is not inconceivable that in the diamond cubic lattice second or higher orders of twins are formed simultaneously or in direct sequence in the course of solidification.

## Graphite-Rod Hairpin-Resistor Radiation Furnace for High Temperatures

by W. J. Kroll, W. W. Stephens, and J. P. Walsted

DISCUSSION, J. P. Nielsen presiding

**C. M. Decroly** (*University of Brussels, Belgium*)—W. J. Kroll and his collaborators are to be congratulated for the beautiful piece of work they are performing at the Bureau of Mines Experiment Station at Albany, Ore. The furnace they describe in their paper is quite interesting and the use of the hairpin graphite resistor is a very good solution of the problem of heating such a furnace. The use of that kind of resistor is not altogether new. In our researches on the thermal metallurgy of zinc carried out in collaboration with Professor O. Dony<sup>9</sup> before World War II in our laboratory, we systematically made use of such types of resistor. They were made by cutting zig-zag graphite plates of the desired thickness with allowance for an increased area at the contact with the water-cooled connections with the copper conductors.

We used them either for internal or external heating for power input up to 20 kw. One of our furnaces was heated with two resistors about 47 in. long. Providing the thickness of the graphite is sufficient, there is no special danger of breakage. The advantages of such resistors are emphasized by the authors. The increase of resistance that can be obtained is very interesting because it is possible to avoid the purchase of a special high intensity transformer. Fig. 3 shows one of the resistors we used in one of our zinc furnaces.

**W. J. Kroll** (authors' reply)—Professor Decroly's observation that the use of a slotted graphite resistor to heat electric furnaces, such as the one described by the authors, is not entirely new, is quite true. Such resistors were used some fifty years ago and the early ironing irons, proposed to housewives around the year 1906, i.e., before the arrival of nichrome resistor elements, were heated with graphite grids precisely of the form recommended later by Professor Decroly himself. Whether such resistors are made by slotting plates or tubes does

<sup>9</sup> O. Dony and C. M. Decroly: *Recherches Théoriques et Expérimentales sur la Métallurgie Thermique du Zinc*. Liège (1933).

Fig. 3—Resistor used in a zinc furnace.

not matter. The Arsem furnace is another typical example of slotting a graphite resistor. The novelty claimed does not reside in the resistor, but in its use for a specific purpose and in the solutions of technical problems concerning its application. Professor Decroly's resistors would probably not perform too well in the high temperature zirconium carbide furnace because of poor contact resulting from the use of plates and high voltage caused by the high resistance. The split rod is simpler, less sensitive, offers better contact opportunities, and has a sufficiently low voltage to prevent arcing in the slot, a very important item when considering the high temperature involved.

# Ignition Temperatures of Magnesium and Magnesium Alloys

by W. Martin Fassell, Jr., Leonard B. Gulbransen, John R. Lewis, and J. Hugh Hamilton

## DISCUSSION, J. P. Nielsen presiding

**T. E. Leontis** (*The Dow Chemical Co., Midland, Mich.*)—This paper is of particular interest to me because of my own work with F. N. Rhines on the oxidation of magnesium and magnesium alloys a few years ago. The authors are to be complimented on their development of an accurate and reproducible technique for measuring ignition temperatures and on their comprehensive study of the many variables that affect the ignition temperature of magnesium.

It is indeed gratifying to see that they have obtained a good correlation between ignition temperatures and the oxidation rates reported by us. The correlation is valid not only with composition within one alloy system but also between alloy systems; that is, alloying elements which effect the greatest increase in oxidation rate also produce the greatest decrease in ignition temperature.

There are a few points upon which I would like to comment. In attempting to correlate ignition-temperature data, one must be sure that the same definition of this quantity is used by all investigators. It does not appear to me that such is the case in the authors' comparison of their data with the theoretically calculated values of Eyring and Zvolinski. The equation derived by these investigators defines the ignition temperature,  $T_0$ , as the temperature at the gas/oxide interface, whereas the present authors use the metal temperature as the criterion for ignition. The contradiction in the effect of oxide-scale thickness on ignition temperature between the predictions of the Eyring-Zvolinski equation and the observations reported in this paper indicate that some variable has not been taken into consideration. Could that be the geometry and size of the specimen? There is a marked difference in the type of specimen used in this investigation and that used in our work which formed the basis of Eyring and Zvolinski's theoretical treatment. Another factor which plays an important role in ignition is the vapor pressure or the rate of vaporization. Combustion can safely be assumed to take place in the vapor phase by the reaction between vaporized magnesium and oxygen. Thus, a more accurate theoretical analysis may be made on the basis of the rate of vaporization which may be the controlling rate of the process.

The effect of a large number of alloying elements on the ignition temperature has been reported in this paper, but beryllium was not included. Practical experience dictates that beryllium markedly decreases the burning tendency of magnesium. I was wondering if the authors plan to study the effect of beryllium in their future work.

The authors predict that concentrations of sulphur dioxide in the furnace atmosphere greater than 5.8 pct would be expected to increase the ignition temperature to values still higher than those they measured. I would like to mention that large concentrations of sulphur dioxide markedly increase the rate of combustion of magnesium once ignition has started. Although it has been shown in the paper that the ignition temperature of magnesium in oxygen increases with increasing sulphur dioxide content up to about 1 to 2 pct, in practice relatively low-melting commercial cast alloys (AZ63A and AZ92A) are being continuously heat treated at temperatures just below the melting point in air containing 0.5 to 0.75 pct  $SO_2$ .

In regard to the change in color of the oxide scale observed on magnesium and magnesium alloys just prior to ignition, I would like to mention that in our work alloying elements were found to color the usually white magnesium oxide even though ignition did not occur. For example, the oxide formed on Mg-Al alloys

was gray, increasing in intensity with aluminum content in the alloy.

Finally, I might suggest that the authors indicate their source of the value of 0.8 g per cc for the density of  $MgO$  as it is formed on magnesium upon oxidation at elevated temperatures.

**W. M. Fassell, Jr.** (authors' reply)—The comments by Dr. Leontis are very excellent ones and I will attempt to answer them in order.

First, the problem of ignition of magnesium is a rather difficult one since many factors are involved. Concerning the comparison of the  $T_0$  in the Eyring-Zvolinski equation, eq 4, with the experimentally determined values, it will be noted that the calculated and experimental values of the ignition temperature in Table I are not self-consistent. In the case of the 1.78 pct Al-Mg alloy the calculated value is  $49^\circ C$  below the experimental value; for the 3.81 pct Al-Mg alloy,  $122^\circ C$  below the experimental value; for Mg with  $5 \times 10^{-2}$  cm film,  $19^\circ C$  above the experimental value; for Mg with  $2 \times 10^{-1}$  cm film,  $28^\circ C$  below the experimental value. Thus, if it were merely a matter of difference of location of temperature measurement the calculated ignition temperature would always be below the experimental value, the difference being due to the thermal gradient through the oxide film.

The possibility of a thermal gradient in the magnesium metal must be considered. From Carslaw and Jaeger,<sup>10</sup> it can be shown that the maximum temperature gradient that could exist between the oxide-metal interface and the center of the sample is of the order of  $0.01^\circ C$ .

The geometry and size of the specimen could certainly have some effect on the ignition temperature. The equation for ignition that has been proposed in reference 14 is of the following type containing terms to account for this and other factors:

$$\Delta H v(T) = C_p \frac{M}{A} \frac{dT}{d\tau} + J(T - T_b) + \Sigma \Delta H_L M$$

where  $\Delta H$  is the heat of reaction,  $v(T)$  is the velocity of the reaction at temperature,  $C_p$  is the heat capacity of sample,  $M$  is the mass of sample,  $A$  is the area of sample,  $\tau$  is time,  $J$  is the total coefficient of heat transfer outward from the reaction zone,  $T_b$  is the temperature of the bath or furnace, and  $\Delta H_L$  is the heat associated with any phase change involved. Prior to the instant of ignition, the vapor pressure of magnesium is of no special significance. After ignition, neither eq 4 nor the above equation is applicable. The actual combination of magnesium cannot safely be assumed to take place in the vapor phase.

While experimental data is lacking to support a hypothesis that ignition does or does not occur in the vapor phase, some observation on the pressure ignition experiments may be of interest. At high oxygen pressures, once ignition has occurred, the reaction of magnesium with oxygen approaches near explosive violence, the entire sample being consumed in probably less than 1 sec. At atmospheric pressure it usually requires 15 to 20 sec. Thus it appears that the oxygen concentration becomes the rate determining factor. Further, if burning magnesium is observed through darkened glass (Lincoln Super-Visibility Shade No. 12) the magnesium sample is very much hotter than the "smoke" and the outline of the sample is retained perfectly. No "flame" is visible above the metal.

No work was done on Mg-Be alloys. We do, however, intend to study this problem in the near future.

<sup>10</sup> H. S. Carslaw and J. C. Jaeger: *Conduction of Heat in Solids*. Oxford (1947), p. 275, eq. 2. Clarendon Press.

Concerning the AZ63A and AZ92A Mg alloys, I assume that you are giving them a solution heat treatment which normally is conducted just below the solidus temperature. Ignition in composition range of AZ62A and AZ92A occurs in oxygen between the

solidus and liquidus temperatures. Thus it is understandable that no difficulties are encountered.

The value of 0.8 g per cc for the density of MgO as it is formed on magnesium upon oxidation was calculated from reference 1, Fig. 16.

## Mechanical Properties of Stainless Steel Powder

by Arthur H. Grobe and George A. Roberts

DISCUSSION, L. A. Barera presiding

**H. H. Hausner** (*Sylvania Electric Products Inc., Bayside, N. Y.*)—I tested the 18-8 stainless steel powder described by Grobe and Roberts and the results were excellent. The powder was compacted and sintered in purified hydrogen to a very low density (approximately 20 pct and more porosity). Where the other powders show very little ductility when sintered to such a low density, the described stainless steel was surprisingly high in ductility. I would appreciate it if the authors could give us some data on a similar powder but without silicon and also data on 430 stainless steel powder.

**H. S. Kalish** (*Sylvania Electric Products Inc., Bayside, N. Y.*)—I should like to verify the excellent results obtained by Grobe and Roberts with their pre-alloyed stainless steel powder. It seems to me, however, that their data are conservative and that even better densities and higher tensile strength can be obtained with these powders by the selection of proper particle size fractions.

The accompanying data were obtained by sintering compacts pressed from the powder made by Vanadium-Alloys Steel Co. to 0.8 in. in diam about ¼ in. high in a cylindrical double action die without the use of lubricant. The compacts were sintered for 1 hr at 2370°F in hydrogen purified by passing it through a Deoxo unit (palladium catalyst) and a Lectrodryer.

Even the density obtained using the as-received (—100 mesh) compacted at 40 tsi was quite high as was the hardness. This indicates that by increasing the sintering temperature slightly above 2350°F the coining and subsequent secondary sintering operation can be avoided.

With the — 325 mesh fraction, however, very much higher density can be obtained and a high hardness.

| Powder Fraction         | Compacting Pressure, tsi | Pressed Density, g per cm <sup>3</sup> | Sintered Density, g per cm <sup>3</sup> | Hardness Rockwell, F |
|-------------------------|--------------------------|----------------------------------------|-----------------------------------------|----------------------|
| —100 mesh (As-received) | 40                       | 5.94                                   | 6.77                                    | 86.9                 |
| —270 + 325 mesh         | 40                       | 5.81                                   | 6.85                                    | 92.3                 |

I have no tensile data to present, but I feel that it is not too optimistic to expect that unusually high tensile strengths and good ductility can be obtained in this sintered material on the basis of the density and hardness data.

The sintered stainless steel made by the above-described methods came out of the furnace very bright and clean. The purified hydrogen atmosphere is important in sintering stainless steel to reduce the oxide present in the powder. The result of such a sintering is good densification and good ductility of the sintered product.

**G. A. Roberts** (authors' reply)—We are greatly indebted to Messrs. Hausner and Kalish for their discussions of our paper. Their encouraging remarks are greatly appreciated and their confirmatory data will do much to add to the value of the paper. At the present time it is impossible to provide complete data on a similar stainless steel powder without silicon, but we do know that, in general, the properties are slightly inferior. Data on such a powder and on other stainless steel types are to be published in the near future.

## Rate of Sintering of Copper Under a Dead Load

by F. N. Rhines and H. S. Cannon

DISCUSSION, L. A. Barera presiding

**H. H. Hausner** (*Sylvania Electric Products Inc., Bayside, N. Y.*)—The results reported by the authors are interesting because they contribute some information on the principles of sintering and also because of a certain practical value for the manufacture of powder metallurgical parts in production. Pressed powder compacts are frequently sintered in a boat in several layers so that the lower layers are actually sintered under the weight of the upper layers and, therefore, are frequently deformed. The authors gave information on this deformation process by determining the effect of the load on the density. The experimental setup of the authors, however, has a disadvantage—that the sintering occurred in a cylindrical container so that the deformation was stopped in the direction of the diameter. The authors should have rather called this a study of hot-pressing than of sintering.

I want to call the attention of the authors and others interested in sintering under load to the experimental work described by Dawihl and Rix.<sup>1</sup> These authors sintered cylindrical compacts under a lengthwise tensional load of 0 to 25 g and found that the shrinkage in length and diameter changes considerably with the load, but that the volume shrinkage is affected very little by the load.

**H. S. Cannon** (authors' reply)—We wish to thank Dr. Hausner for calling attention to the experimental work of Dawihl and Rix. The fact that they found volume shrinkage little affected by varying tensional loads during sintering seems to support the contention that the forces due to loading are equivalent to and additive to the forces which cause densification. This contention is the basis of our comparison of sintering and creep.

# Recovery of Vanadium from Titaniferous Magnetite

by Sandford S. Cole and John S. Breitenstein

The recovery of over 80 pct of the vanadium values in titaniferous magnetite from MacIntyre Development, Tahawus, N. Y., was accomplished by an oxidizing roast with  $\text{Na}_2\text{CO}_3$ - $\text{NaCl}$  addition. Process description is given for leaching of roasted ore and precipitation of  $\text{V}_2\text{O}_5$  and  $\text{Cr}_2\text{O}_3$  from leach liquor.

THE exploration and development of the MacIntyre orebody at Tahawus, N. Y., by the National Lead Co. provided a source of vanadium. Analyses of various composite sections of the drill cores of the MacIntyre orebody were made to establish whether or not the vanadium was constant throughout. Ten drill cores were sampled as 50 ft sections, crushed, and a portion magnetically concentrated. The head and concentrate were analyzed for total iron and vanadium. The results on the concentrates indicated that the vanadium is associated with the magnetite and maintains a close ratio to the iron content. The nominal ratio of 1:25:140 of V:TiO<sub>2</sub>:Fe was found to exist in the concentrates. Typical value for the vanadium in the magnetite both from laboratory concentration and mill production is 0.4 pct.

The recovery of vanadium from the magnetite was investigated in 1942 to 1943. The research program encompassed both laboratory and pilot-plant work on sufficient scale to provide adequate data to establish the feasibility of a full scale plant.

The recovery of vanadium from various ores has been reported in the literature and has been the subject of many patents. The literature dealing with recovery from titaniferous ore by roasting is quite limited. Roasting with alkaline sodium chloride, sodium chloride or alkaline earth chlorides, and sodium acid sulphate have been claimed in various processes as effective means.<sup>1-8</sup> The reduction of the ore, followed by acid leaching, was another method proposed.<sup>9-10</sup> The use of various pyrometallurgical processes for recovery of vanadium in the metal or in the slag has also been extensively investigated, but the results had little application to the problem.<sup>11-14</sup> The separation of vanadium values from subsequent leach liquors and vanadium-bearing solution has been the subject of a considerable number of papers and patents. The most practical is by hydrolysis at a pH of 2 to 3 by acidifying a slightly

alkaline solution. Data on solubility of  $\text{V}_2\text{O}_5$  and  $\text{V}_2\text{O}_4$  in water and in dilute sulphuric acid indicated a solubility of 10 g per liter in water.<sup>16</sup>

## Laboratory Results

**Magnetite Analysis:** Adequate stock of magnetite was provided so that the laboratory and pilot-plant operation was on ore representative of the mill production. The ore was analyzed chemically and examined by petrographic methods to ascertain whether the vanadium was present in combined state or as an interstitial component between grain boundaries. No evidence was obtained which would indicate that the vanadium was in a free state as coulsonite.<sup>15</sup> The analysis of the ore was as follows: Fe<sub>2</sub>O<sub>3</sub>, 47.4 pct; FeO, 29.1; TiO<sub>2</sub>, 10.1; V, 0.40; and Cr, 0.2.

The screen analysis of the ore on the as-received basis was: -20 +30 mesh, 28.8 pct; -30 +40, 18.9; -40 +50, 9.7; -50 +60, 15.1; -60 +100, 5.9; -100 +200, 11.2; -200 +325, 3.7; and -325, 7.2.

**Roasting Conditions:** The prior practice indicated that a chloridizing roast with or without an alkaline salt had been effective on other titaniferous magnetites. On this basis roasts with additions of sodium chloride, sodium carbonate and mixtures thereof were investigated varying the roasting temperature between 800° and 1100°C. Since the ore had shown no segregation or concentration of vanadium, the influence of particle size on the freeing of vanadium by the reagents during roasting was determined. The initial work was on silica trays in an electric resistance furnace with occasional rapping of the charge. Subsequently, the roasting was carried out in a small Herreshoff furnace to establish the influence of products of combustion on the recovery of the vanadium.

The laboratory tests showed that this ore required an alkaline chloridizing roast, in conjunction with a reduction in particle size to less than 200 mesh. When roasted in air at 900°C with 5 pct NaCl and 10 pct Na<sub>2</sub>CO<sub>3</sub>, over 80 pct recovery of the vanadium was attained as a water-soluble salt. The presence of alkaline earth elements gave detrimental effects and care had to be exercised to avoid any contamination of the ore or roast product by such materials.

The solubilization of vanadium under the various conditions is given in a series of curves in Figs. 1 to

S. S. COLE, Member AIME, is Assistant Manager of Research, Titanium Div., National Lead Co., South Amboy, N. J., and J. S. BREITENSTEIN, Member AIME, Supervisor, Geochemical and Metallurgical Dept., Research Dept., Titanium Div., National Lead Co., South Amboy, is presently with National Lead Co. of Ohio, Cincinnati.

Discussion on this paper, TP 3177D, may be sent, 2 copies, to AIME by Feb. 1, 1952. Manuscript, Feb. 22, 1951; revision, Sept. 28, 1951. St. Louis Meeting, February 1951.

Fig. 1—Effect of roasting as-received ore with NaCl at 950°C.

Fig. 2—Effect of roasting ground ore with NaCl at various temperatures.

6. The influence of the several factors is quite apparent. The general conditions for processing the ore as determined by the roasts are shown in Table I.

**Leaching Conditions:** Leaching of the roasted ore was varied using percolation and countercurrent washing. The retention of solution on the ore was not found to be critical since the vanadium-bearing salts were on the surface of the ore particle. The use of countercurrent stages for leaching was desirable since the concentration of vanadium could be increased to 10 to 20 g per liter, thus reducing the volume of liquor in process. Four to five stages of leaching removed 98 to 100 pct of the soluble vanadium. The increase in vanadium content of the leach liquor is shown in Fig. 7 when the leaching was carried out for six stages. Crushing the consolidated lumps to -10 mesh and avoiding forming of -100 mesh material yielded the optimum product. Large amounts of -100 mesh material gave a slow rate of filtration. The rate of diffusion of the leach liquor into lumps coarser than 10 mesh retarded the rapid removal of the soluble vanadium. The use of water at 80°C was found to give a slight improvement, especially in conjunction with suppression of aluminum salts.

#### Recovery of Vanadium and Other Values

The leach liquor from a chloridizing alkaline roast contained the vanadium as a sodium vanadate, sodium chromate, sodium aluminate, sodium chloride, sodium carbonate, and sodium sulphate. The cyclic recovery of sodium values was desirable and elimination of aluminum salts was necessary. The suppression of aluminum during leaching by a carbon dioxide atmosphere was found to be the most satisfactory.

Precipitation of vanadium as a calcium vanadate complex in presence of  $\text{CaCl}_2$  and  $\text{Ca(OH)}_2$  was satisfactory for leach liquors derived from salt roast or when the liquors were low in sulphur values. The optimum ratio by weight of reagents to vanadium was  $2\text{Ca(OH)}_2:\text{V}$  and  $1-1.4\text{CaCl}_2:2\text{V}$  with-

out altering the pH of the leach liquor. This procedure had considerable merit when working with solutions having vanadium at low concentrations of the order of 0.5 to 5 g per liter.

Hydrolysis of vanadium from the leach liquor was based upon the use of nucleating conditions and adjusting the pH to  $2.5 \pm 0.2$ .<sup>18, 19</sup> The solution was acidified with sulphuric acid at room temperature and up to 80°C. The temperature was held at 95°C for 1 hr and then the solution was boiled for an additional hour. The acidification was done without agitation over a 10 min period. The slow formation of nuclei of  $\text{V}_2\text{O}_5$  occurred and on subsequent heating and agitation large nodules or flocs of 1/16 to 1/4 in. diam formed. No appreciable formation of  $\text{V}_2\text{O}_5$  occurred below 85°C. This practice avoided the adherence of vanadium oxide to the side walls of the vessel and the product was easily filtered and washed. The removal of vanadium was over 99 pct.

The filtrate was reduced with  $\text{SO}_2$  and the solution adjusted with  $\text{Na}_2\text{CO}_3$  to a pH of 7.0, thereby hydrolyzing chromium as  $\text{Cr(OH)}_3$ . The filtrate from this step contained only sodium chloride and sodium sulphate which was readily crystallized and separated in pure state in accordance with published data.<sup>20</sup> The sodium chloride liquor containing some sodium sulphate could be returned to the process

Fig. 3—Effect of roasting ground ore with NaCl at 1000°C.

without adversely affecting the vanadium recovery since it contained only these compounds. The new salt makeup was 60 pct of the total requirement.

#### Pilot-Plant Operation

Based on laboratory results and procedures, process flowsheets were devised so as to adapt the existing pilot-plant equipment to the problem. In several instances improvisation was necessary and conditions indicated by laboratory practice were not met fully. This was particularly true in the case of leaching. Laboratory tests had indicated fast filtering equipment, but none was available so barrels were substituted and the solution transferred from one stage to the next. The roasting was done in a 3x30 ft rotary kiln, fired with Bunker "C" oil. The

Fig. 5—Effect of roasting ground ore with  $\text{Na}_2\text{CO}_3$  at 1000°C.

Fig. 4—Effect of roasting ground ore with  $\text{Na}_2\text{CO}_3$  at various temperatures.

processing of roasted ore and leach liquor was on a scale comparable to a half ton of feed ore per 6 hr.

The flowsheet for the recovery of vanadium from the MacIntyre magnetite utilizing  $\text{NaCl-Na}_2\text{CO}_3$  mixtures for the pilot-plant operation is given in Fig. 8. The specific conditions for each stage of the process are discussed in separate sections.

**Ore Grinding and Blending:** A small Raymond mill capable of grinding 500 to 600 lb per hr was used to prepare a feed for the rotary kiln which was comparable with ball mill ground ore. The differences in screen size were less than 2 pct of the product used for laboratory roasts.

The blending of the reagents with the ore was accomplished with a flight mixer using sufficient

Fig. 6—Effect of roasting ground ore with  $\text{Na}_2\text{CO}_3\text{-NaCl}$  mixtures at 900° and 950°C.

water to prevent dust losses. This gave an even distribution of reagents through the ore. The mixture was then blended with water to produce a mass having 12 to 16 pct moisture. This served a dual purpose, since the reagents would be in better contact with the ore and the charge would form as balls or lumps in the kiln. The formation of lumps reduced the loss of sodium chloride during the roasting operation.

*Roasting Operation:* A bed of ore of 3 to 10 in. was maintained in the kiln which had 24 in. ID. The kiln temperatures were varied to determine what the optimum would be for pilot-plant as compared with laboratory scale. The results indicate 910° to 920°C with 1 to 2 hr retention time at that temperature. The lumps which formed about 90 pct of the discharge gave better recovery of vanadium. Table II shows the differences in retention time, temperature, and conditions of discharge.

The data obtained indicated that the general specification for kiln conditions would be as follows:

|                |                                    |
|----------------|------------------------------------|
| Temperature    | 910°-930° ± 10°C                   |
| Retention time | 45-75 min                          |
| Bed thickness  | 6 in. minimum<br>12-24 in. maximum |
| Stack gas      | 2-7 pct O <sub>2</sub>             |
| Type of feed   | Nodules ½-3 in. diam               |
| Feed bulk      | 120-130 lb per cu ft               |

In order to determine what may have contributed to the differences in recovery of vanadium from the lumps vs. fines, a complete analysis was made from

Table II. Results of Roasting

| Retention Time, Hr | Temperature, °C | Vanadium Recovery, Pct |       |
|--------------------|-----------------|------------------------|-------|
|                    |                 | Lumps                  | Fines |
| 0.5                | 910             | 73                     | 48    |
| 1.0                | 910             | 94                     | 58    |
| 1.0                | 940             | 83                     | 67    |
| 2.0                | 910             | 77                     | 80    |
| 2.0                | 920             | 89                     | 66    |
| 2.0                | 950             | 89                     | 58    |

one 24-hr operation and partial analysis of several other shorter periods. The only difference observed was in the soluble NaCl content which was considerably lower in the fines, of the order of 0.9 to 1.0 pct while lumps gave 1.4 to 1.8 pct.

Analyses on dry basis of a typical composite before and after leaching of the furnace discharge are given in Table III.

Table III. Analyses of Typical Composite of Leach

|                                | Unleached, Pct | Leached, Pct |
|--------------------------------|----------------|--------------|
| TiO <sub>2</sub>               | 8.9            | 9.1          |

|                                | <hr/> 99.21    | <hr/> 99.93  |

*Leaching Roasted Ore:* The lumps were crushed to pass a 6 mesh screen and 500 lb placed in wooden barrels equipped with drainage spouts. The initial water started through the leaching cycle was 80 gal per ton roasted ore with 34 gal per ton ore being recovered from the cycle due to porosity of the lumps and retention on the ore. The final liquor averaged 17 g per liter vanadium. Comparison of laboratory leaching efficiency with that of the pilot plant gave equivalent recovery of vanadium. Results of comparison of leaching recovery with first

Fig. 8—Flowsheet for pilot-plant process.

and last stage showed 99.0 pct efficiency. Data on the leaching operation are as follows:

#### Comparison of First and Last Stages

|                                  |           |
|----------------------------------|-----------|
| Vanadium in first stage liquor   | 20.458 lb |
| Vanadium in last stage liquor    | 0.444     |
| Vanadium in solution held by ore | 0.20      |
| Vanadium lost in solution on ore | 0.98 pct  |

#### Conditions for Leaching

#### Analysis of Leach Liquor

|                                 |                     |
|---------------------------------|---------------------|
| Specific gravity                | 1.25-1.28 at 25°C   |
| pH                              | 8.8-9.0             |
| V                               | 16-20 g per liter   |
| Al <sub>2</sub> O <sub>3</sub>  | 0-0.2 g per liter   |
| Cr                              | 2-4 g per liter     |
| Na <sub>2</sub> SO <sub>4</sub> | 120-140 g per liter |
| NaCl                            | 75-120 g per liter  |
| Temperature of leaching         | 60-80°C             |
| Ore size, -4 mesh               | 100 pct             |
| -100 mesh                       | <10 pct             |
| Retention time, first stage     | 20 min              |
| balance                         | 1-5 min             |
| Moisture, leached residue       | 14-18 pct           |

**Recovery of Metal and Salt Values from Leach Liquor:** A series of pilot-plant precipitations were made using composited lots of leach liquor. Analysis of the filtrates after each stage of vanadium and chromium removal showed over 99 pct effective removal.

Optimum conditions for recovery of the metal values based upon pilot-plant runs were found to be as follows:

#### V<sub>2</sub>O<sub>5</sub> Precipitation

|                                                  |                                               |

#### Cr<sub>2</sub>O<sub>3</sub> Precipitation

|                                                              |                                       |
|--------------------------------------------------------------|---------------------------------------|
| SO <sub>2</sub> per kg Cr                                    | 3                                     |
| Na <sub>2</sub> CO <sub>3</sub> per kg Cr                    | 4                                     |
| Temperature for reduction                                    | 60°-90°C                              |
| pH after Na <sub>2</sub> CO <sub>3</sub> addition            | 6.5-7.0                               |
| Temperature for Cr <sub>2</sub> O <sub>3</sub> precipitation | 70°-100°C                             |
| Rate of temperature rise                                     | Not critical                          |
| Time at 95°-100°C                                            | 1-3 hr                                |
| Wash water for Cr <sub>2</sub> O <sub>3</sub>                | ¼-½ volume of filtrate                |
| Floc volume                                                  | 15 pct                                |
| Filtration rate for Cr <sub>2</sub> O <sub>3</sub>           | 0.13 g per sq cm per hr               |
| Solids in cake                                               | 21.2 pct                              |
| Analysis of calcine                                          | 99 pct Cr <sub>2</sub> O <sub>3</sub> |

#### Filtrate from Cr<sub>2</sub>O<sub>3</sub> Precipitation

The filtrate available for sodium sulphate recovery had the following typical analysis from a 15 g per liter vanadium starting solution:

|                                 |                   |
|---------------------------------|-------------------|
| Volume increase                 | 15 pct            |
| pH                              | 6.5               |
| Na <sub>2</sub> SO <sub>4</sub> | 200 g per liter   |
| NaCl                            | 65 g per liter    |
| Cr                              | <0.01 g per liter |
| Specific gravity                | 1.2               |

Since this liquor could be concentrated and pure Na<sub>2</sub>SO<sub>4</sub> crystallized in a standard unit, it was not considered necessary to follow out this step.

#### Summary

A process developed in the laboratory and carried through the pilot-plant for the recovery of vanadium values from MacIntyre magnetite containing 10 pct TiO<sub>2</sub> and 0.4 pct V has been described. Grinding the ore to pass 200 mesh screen is required. The addition of 3 to 5 pct NaCl and 6 to 10 pct Na<sub>2</sub>CO<sub>3</sub> is made and roasting is under oxidizing conditions at 910° to 930°C. The effective release in soluble form of 75 to 90 pct of the vanadium contained and 50 pct chromium was accomplished by this roast.

The leaching of the roaster discharge in the presence of stack gases fixed the aluminum values in the leach cake. Conditions for precipitation of a fast filtering vanadium oxide by use of nuclei at a pH of 2.5 were established. The precipitation of chromium hydroxide after reduction of the solution with SO<sub>2</sub> at a pH of 6.5 to 7.0 yielded a sodium sulphate-sodium chloride liquor from which pure sodium sulphate was crystallized and the sodium chloride brine was returned to process. Recovery of vanadium and chromium values from the solutions was over 99 pct effective.

#### Acknowledgments

The authors wish to acknowledge the assistance given during the laboratory and pilot-plant phases by R. L. Holiday, W. F. Meister, C. H. North, and L. W. Rowe, Research Chemists of the Research Dept., and advice of J. L. Turner, Technical Director (deceased) and R. Dahlstrom, Technical Director, Titanium Div., National Lead Co.

# Low Grade Bauxites and Clays as Potential Aluminum Resources

by K. K. Kershner, C. W. Funk, and W. A. Calhoun

Future resources of aluminum may require the utilization of low grade ores to provide a more permanent protection for the nation. Aluminum minerals such as clay, shale, and high iron laterites may become important sources. An evaluation of reserves is given. New laboratory results are reported on the Vereinigte desilication process.

THIS report on future resources of aluminum metal emphasizes the necessity for investigating utilization of low grade potential ores to provide more permanent protection for the nation. Partial or complete interruption of the importation of high grade aluminum ores must be given consideration. Ultimately, aluminum minerals such as clay, shale, and high iron laterites may become the principal sources of aluminum. The development of extractive processes for treating these low grade materials is a step in long-range national preparedness that should receive more attention. In formulating such processes, the application of beneficiation methods for the purpose of classifying the several types of minerals before subjecting each type to the more expensive extractive procedures should be considered, and a careful survey of the basic factors of power sources, transportation facilities, and sources of raw material should be made.

## Domestic Bauxite Resources

Of the domestic supply of current, treatable-grade bauxite, 95 pct comes from Arkansas. The present reserve of Arkansas bauxite suitable for metal production, including abrasive-grade, Bayer-grade, and modified Bayer-grade ores, is 34,000,000 tons. The total reserve of bauxite of all grades is approximately 75,000,000 tons. Reserves are estimated on a mined and dried basis. Data available to the Bureau of Mines in 1948 to 1949 were used in preparing Table I, which shows a breakdown by grades of bauxite for about a half of the reserves of the state.

The modified Bayer ore, 10,555,500 long dry tons, is based on a cutoff of 8 to 15 pct silica. The sub-

Table I. Arkansas Bauxite Reserves in Deposits for which Data Were Made Available to Bureau of Mines as of Dec. 31, 1948

| Grade          | Wet Long Tons<br>in Place | Mined Dry<br>Long Tons |
|----------------|---------------------------|------------------------|
| Abrasive       | 2,863,500                 | 1,634,200              |
| Bayer          | 9,653,500                 | 5,422,000              |
| Modified Bayer | 18,497,900                | 10,555,500             |
| Subtotals      | 31,014,900                | 17,611,700             |
| Marginal metal | 7,823,300                 | 4,347,000              |
| High iron      | 8,334,300                 | 4,580,100              |
| Chemical       | 1,829,600                 | 1,145,000              |
| Submarginal    | 17,777,500                | 10,074,700             |
| Grand total    | 66,779,600                | 37,758,500             |

marginal 10,074,700 long dry tons is assumed to contain more than 40 pct gibbsite, more than 15 pct silica, and less than 32 pct available alumina. A considerable amount of this low grade material was consumed in 1949 and 1950.

Additional tonnages of bauxitic and kaolinitic clays are indicated by the Bureau of Mines drilling project.<sup>1</sup> Applying a 50 pct factor to arrive at long tons mined and dried, the results of this project are approximately 31,500,000 tons kaolinitic clay at +35 pct  $\text{Al}_2\text{O}_3$  and 11,800,000 tons kaolinitic clay at 20 to 35 pct  $\text{Al}_2\text{O}_3$ .

Total reserves of kaolinitic clays are probably quite extensive—several times the reserves shown in the Bureau's work. Total reserves of bauxitic and high iron clays from the drilling program and previously established figures are 63,980,000 tons.

The mineral dressing methods,<sup>2</sup> the lime-sinter process,<sup>3</sup> the lime-sinter modification of the Pederson process,<sup>4</sup> the lime-soda sinter process,<sup>5-8</sup> and the Alcoa combination process<sup>9, 10</sup> have been described in the literature and will not be elaborated upon here. The less familiar Vereinigte Aluminium-Werke process used by the Germans during World War II may require some amplification. It was used to beneficiate boehmite ores containing 12 to 18 pct silica for a feed to the European Bayer process. Ore was

reported to be calcined at 900° to 1000°C (1652° to 1832°F) to decompose kaolin to amorphous silica and alumina. The calcine was crushed to 15 mm to be suitable for percolation and was leached with a recycled 10 pct sodium hydroxide solution at 90° to 95°C (194° to 203°F) to dissolve the silica. As much as 80 pct of the silica was extracted, and as little as 2 pct of the alumina was lost. Soda was regenerated by adding lime and precipitating dicalcium silicate. The desilicated residue was treated by the European Bayer process in the same reactor.<sup>11, 12</sup>

#### Bureau of Mines Research Work—1950

Preliminary laboratory tests on the percolation leaching of silica from bauxites by the Vereinigte process<sup>11</sup> were reported by Skow and Conley,<sup>12</sup> of the College Park laboratories. Approximately 65 to 80 pct of the silica and 8 to 11 pct of the alumina were removed from bauxites containing 11.9 to 22.2 pct silica.

This desilication process is being investigated at the Rolla, Mo., and Bauxite, Ark., laboratories of the Bureau of Mines. As the silica content of low grade bauxites and clay is largely in the form of hydrous aluminum silicates, the preliminary experiments have dealt with kaolinite and halloysite.

Differential thermal analysis curves made on samples of these materials showed endothermic and exothermic peaks at 595° and 596°C (1103° and 1105°F) and 965° and 969°C (1769° and 1776°F), respectively. These two peaks correspond to the loss of water of hydration<sup>13, 14</sup> and to a transitional or transformation reaction.<sup>15, 16</sup> The two samples contained 42 and 45 pct silica and 37 and 38 pct alumina, respectively.

The samples were dry-ground in a pebble mill to -100 mesh and calcined at different temperatures

within a range of 400° to 1000°C (752° to 1832°F) for 2 and 4 hr periods. The calcines were agitated with 10 pct sodium hydroxide at 90° to 95°C (194° to 203°F) for 1 hr.

The distribution of silica and alumina in leach solutions and residues is summarized in Tables II and III. The available alumina, which is the quantity of the desilicated residue dissolved by pressure digestion with 10 pct caustic at 148°C for 10 min, and analyses of calcines also are given. The data are average values obtained from several tests.

These tables indicate that calcination above 900°C (1652°F) is required to extract an appreciable amount of silica. Below 900°C (1652°F) the silica extraction is less than 30 pct of the original content; simultaneously, approximately the same percentage of alumina is dissolved, part of which might be recovered by re-treating the leach solution. The amount of available alumina in the desilicated residues is substantially zero.

Calcination at 950°C (1742°F) affects a marked change in the percentage of soluble silica and alumina in the 10 pct caustic. It will be noted that 74 to 85 pct of the original silica is removed from calcines prepared at 950° and 1000°C (1742° and 1832°F) with the simultaneous solution of approximately 10 pct of the total alumina. In a cyclic process, a portion of this dissolved alumina would be returned as sodium aluminate with the sodium hydroxide liquor obtained from the causticization with lime to remove silica. The data also show a silica content of 12 pct in the kaolinite leach residues, as compared to 20 pct in those from the halloysite. The Vereinigte process shows reductions in silica content of 75 to 82 pct accompanied by alumina removals of 1 to 2 pct, and large-scale tower desilications produced desilicated material containing approximately

Fig. 1—Influence of silica content of ore on alumina recovery and reagent costs.

6 pct silica. The need for further investigation with variable leaching conditions is indicated by the removal of 10 pct alumina during desilication.

When calcination of the halloysite at 950°C (1742°F) was lengthened from 2 to 4 hr, silica extraction was improved without materially affecting the solubility of the alumina, and the alumina soluble by pressure digestion was increased. Raising the temperature of calcination of the kaolinite from 950° to 1000°C (1742° to 1832°F) decreased the alumina removal without affecting the silica extraction and somewhat increased the available alumina.

There are differences of opinion concerning the material resulting from the dehydration of hydrous aluminum silicates. Insley and Ewell<sup>16</sup> state that amorphous silica and amorphous alumina are formed; Vernadskii<sup>17</sup> says that kaolin anhydride is produced; and Hyslop<sup>18</sup> considers that kaolinite completely breaks down around 600°C (1112°F) to form a silicate stable to about 900°C (1652°F). X-ray examination of calcines and desilicated residues in this investigation shows that an amorphous condition follows dehydration. Calcines prepared at 600° to 800°C (1112° to 1472°F) were as resistant to increased silica extraction with 10 pct caustic as those produced at 400° and 500°C (752° and 932°F).

Experiments were conducted on the dehydration of halloysite under reduced pressures and lower temperatures in order to investigate the properties of the resulting products. It was thought that the release of chemically combined water under such conditions might yield a product more amenable to desilication. However, these calcines gave no definite X-ray patterns, and there was no material difference in their solubility from those produced under normal conditions.

X-ray patterns of calcines and leach residues showed the presence of mullite when calcinations above 900°C (1652°F) were made. Though quantitative measurements were not made, the amount of mullite appeared to increase with higher temperatures and longer calcination. The formation of mullite in the desilication process has not been reported

previously, although its presence in fired kaolinite has been reported by other investigators.<sup>19-21</sup> Comofore, Fischer, and Bradley<sup>22</sup> describe the formation of mullite as due to the collapse of a noncrystalline skeletal anhydride to produce a more stable crystalline form when kaolinite is fired to approximately 1000°C (1832°F). The formation of mullite renders a portion of the silica resistant to the caustic treatment and probably causes some reduction in available alumina. X-ray diffraction also reveals the presence of  $\gamma$  alumina in the calcines and leach residues.

The results of the preliminary work on kaolinite show that by calcination and leaching with 10 pct caustic solution, 85 pct desilication may be expected with alumina losses of approximately 10 pct. Although the silica extraction is higher, the alumina losses are substantially greater than those reported for the Vereinigte Aluminium-Werke process. The desilicated product, which averages 68 pct alumina, with slightly less than half of it soluble by pressure digestion, cannot be considered a suitable feed for the Bayer process. Consideration may be given to this material as a feed to either the combination or lime-soda process. The desilication treatment is also open to speculation if applied to ores of lower silica content. The preliminary results are considered definite enough to warrant additional fundamental investigations with variable conditions of calcination to minimize the formation of mullite, and also with leaching procedures to reduce alumina losses in desilication.

In addition to kaolinite, bauxitic and kaolinitic clays with various amounts of gibbsite (both in naturally occurring ores and synthetic mixtures) will be included in future investigations. The calcination experiments will involve a more detailed consideration of heating rate as well as the temperature within the region of the exothermic reaction as determined by differential thermal analysis. Comparative tests will also be made on pelletized calcines, percolation, counterflow, and multiple-stage leaching, and determination of solution stabilities. These data will be necessary for a complete evaluation of the Vereinigte Aluminium-Werke process when applied to domestic high silica potential aluminum resources.

### Process Comparison

A comparison of the potential position of the Vereinigte Aluminium-Werke desilication process relative to the modified Bayer, or Alcoa combination process, and the lime-soda sinter processes was evaluated in terms of the especially significant factors, alumina recovery and reagent cost. Although the less tangible factors of labor, plant installation, and fuel costs would appreciably influence any economic analysis, these considerations were not included in the comparison. The German and Alcoa procedures utilize stages of the Bayer and lime-soda sinter processes, and assumptions for these common stages were the same. Hypothetical feeds containing proportions of kaolinite and gibbsite were used to simplify the comparison.

The chemical and physical principles of the Vereinigte Aluminium-Werke process are not thoroughly established; therefore, the best results from the published German tests<sup>11</sup> were used in the evaluation. In this work, 80 pct of the silica was extracted with an alumina loss of only 2 pct, and a lime consumption of 3 mols per mol of silica ex-

tracted was assumed in the comparison. The Bayer digestion was assumed to recover 100 pct of the alumina that was not converted to insoluble sodium aluminum silicate. Corresponding portions of alumina and soda were considered to be rejected to red mud. Although alumina recoveries for the lime-soda sinter process of 86 to 89 pct have been obtained,<sup>6</sup> other authorities have expressed the opinion that commercial operations using high silica feeds would approach an alumina recovery of 80 pct. Although the latter figure may be slightly pessimistic, it was assumed for the calculations along with a rejection of 98 pct of the silica to the brown mud, a lime consumption of 200 pct, and a soda consumption equivalent to 7 pct of the silica removed.

The calculations are based on the treatment of the residue from the German desilication procedure by an appropriate Bayer digestion, the red mud from which would be re-treated by a lime-soda sinter and the leach liquor returned to the Bayer digestion. Calculations for the modified Bayer are on the normal flow circuit. Those for the lime-soda sinter are based upon the alumina being extracted by Bayer digestion. To provide a basis for comparison, lime requirements were converted to limestone at an assumed value of \$2 a ton, and soda ash was valued at \$24 a ton (f.o.b. August 1950). Trends resulting from these estimates are illustrated in Fig. 1, which plots alumina recovery and reagent costs against increasing silica content of the ore.

Estimated alumina recovery from the modified Bayer process decreases rapidly, and reagent cost increases over sixfold as the silica content of the ore increases. If ore is fed directly to a lime-soda sinter plant, alumina recovery is relatively unaffected by increased silica content in the ore, and recovery cannot be expected to exceed 80 pct due to a 20 pct alumina loss in the first step of the process. Reagent costs for the direct lime-soda process are slightly higher than for the modified Bayer. Although alumina recovery for all processes decreases as the silica content of the ore increases, the recovery curve of the VAW process is the least affected. As a result of higher alumina recovery, the reagent costs of the VAW process are the most favorable.

Consideration may be given to the curves on the basis of an assumed alumina recovery in the lime-soda process of 90 pct. The recovery curve of the lime-soda sinter method would be displaced about 10 pct upward. As the modified Bayer and Vereinigte Aluminium-Werke calculations also depend on alumina recovery of the lime-soda sinter procedure, a proportional upward shift in these curves would also be obtained. Similarly, the reagent cost curves would be displaced downward for each process. It is then apparent that the absolute location of each curve depends on rather arbitrary assumptions, but the relative slope and relative position of each curve is inherently characteristic of the process.

### Conclusions

Mineral-dressing methods are limited in their present technology by the colloidal character of the ore and the chemical association of alumina with silica in clays. When necessity requires the use of varied and complex ores, classification techniques that depend on physical differences of the materials may be useful for rejecting impurities to produce a smaller volume of feed of superior quality for subsequent extractive operations.

Any alkaline process will require large tonnages

of high calcium limestone in the vicinity of the treatment plant to treat high silica ore. Direct feed of ore to a lime-sinter process is believed, by one school of thought, to be the best method currently available for treating high silica ore, as it avoids the large circulating load of soda.

Although there may be no technical limit to the modified Bayer process, as some authorities maintain, current economics dictate 13 pct as the maximum silica content in the ore unless soda is regenerated by carbonation, in which case 18 pct silica is the maximum. The increased tonnage of red mud caused by high silica ore reduces the tonnage of alumina that can be produced from an installation of a given sinter-plant capacity. If the VAW desilication procedure is capable of yielding a suitable feed to a Bayer process, the silica limit of aluminum ore could again be increased significantly with a subsequent expansion of available domestic resources.

An industrial and military preparedness program requires consideration of suddenly disrupted imports and ultimate depletion of domestic high grade bauxite. The technology of winning aluminum from domestic clays must be developed to meet such circumstances.

Further consideration of the Vereinigte process should include a more detailed study of conditions for calcination of kaolinitic and bauxitic clays to minimize mullitization, and an investigation of various leaching procedures to lessen alumina losses during desilication. Pilot-plant operations should follow promising laboratory experimental results and economic evaluations before commercial applications are considered.

### Acknowledgments

The authors gratefully acknowledge the helpful suggestions and contributions regarding the economic and technical aspects of the extraction processes by R. B. Derr, General Manager, Aluminum Ore Co., St. Louis, Mo.; W. W. Binford, Manager, Reynolds Metals Co., Hurricane Creek Plant, Bauxite, Ark., and their staffs. Estimates of ore reserves were furnished through the cooperative efforts of B. M. Reynolds, Mining Engineer, and L. T. McElvenny, Chief, Mining Branch, Minerals Technology Division, Region VI, U. S. Bureau of Mines, Rolla, Mo.

Technical Note

Crystallographic Angles for Tin

by J. F. Nicholas

THE angles between the crystallographic planes in cubic metals were originally given by Bozorth<sup>1</sup> and have been republished many times. Recently, Salkovitz<sup>2</sup> tabulated the angles for the hexagonal metals (magnesium, zinc, and cadmium). The most commonly used metal which does not fall into either of these groups is tin, which has a tetragonal structure with an axial ratio of  $c/a = 0.54558$  (99.99 pct purity, 25°C).<sup>3</sup> Accordingly, Table I has been prepared giving the possible values for the angle,  $\phi$ , between planes of the types  $\{HKL\}$  and  $\{hkl\}$ . The formula used was:

$$\cos \phi = \frac{Hh + Kk + Ll \frac{a^2}{c^2}}{\left[ \left( H^2 + K^2 + L^2 \frac{a^2}{c^2} \right) \left( h^2 + k^2 + l^2 \frac{a^2}{c^2} \right) \right]^{1/2}}$$

All angles are given correct to the nearest minute as this is sufficient for all practical purposes. Every angle depends in a different way on variations in the value of  $c/a$ , but even in the worst cases a variation of about 0.0003 in this ratio is needed to vary an angle by 1', which corresponds to a temperature change of 20°C or can be caused by impurities.

# Mechanism of Grain Refinement in Aluminum Alloys

by F. A. Crossley and L. F. Mondolfo

The mechanism of grain refinement by the addition of small amounts of titanium, molybdenum, zirconium, tungsten, and chromium to aluminum was investigated. The results indicate that the grain refinement is caused by the peritectic reaction which, by transforming the intermetallic compound into crystals of aluminum solid solution, seeds the melt with nuclei above the freezing point of aluminum.

THE feasibility of reducing the grain size of aluminum alloy castings by the addition of small amounts of titanium, zirconium, molybdenum, tungsten, columbium, boron, and chromium has been known for a long time, and the use of some of these elements as grain refiners is common practice in the aluminum foundry industry. The purpose of the present investigation was to determine the mechanism by which these additions produce the grain refinement.

Asato et al.,<sup>1-5</sup> on the basis of extensive work on copper, antimony, and silver alloys, presented a theory of grain refinement based on the occurrence of the peritectic reaction. Briefly, this theory states that during cooling of the melt crystals of the primary phase form, which react peritectically with the liquid upon further cooling. The peritectic reaction transforms at least partially the primary crystals into crystals of the secondary phase, which then act as nuclei for solidification of the remaining melt. As the peritectic reaction takes place the primary crys-

tals break in pieces, and each piece acts as a nucleus. Fine dendritic crystals which can easily break are the most effective for grain refinement.

Sicha and Boehm,<sup>6</sup> in investigating the refining effect of titanium on an Al-Cu alloy, concluded that  $TiAl_3$  crystals serve as nuclei to initiate crystallization, but did not offer further information on the mechanism of refinement. Bonsack in the discussion of their paper suggested that refinement was due to clouds of some solid in the melt, probably  $TiO_2$  which hindered grain growth.

Eborall,<sup>7</sup> after studying the effect of titanium, zirconium, vanadium, tungsten, columbium, chromium, and boron on some alloys, concluded that the peritectic reaction was not an essential feature of grain refinement. Her conclusion was based mainly upon the observation that under her experimental conditions (sand casting) the Al-Cr alloys, which undergo a peritectic reaction, did not show appreciable refinement.

Cibula<sup>8</sup> investigated the mechanism of grain refinement and reported that two types of grain refinement exist: 1—Grain refinement produced by restriction of grain growth by the concentration gradient mechanism proposed by Northcott.<sup>9</sup> 2—Grain refinement produced by the presence of particles in the melt, upon which the melt crystallizes easily. He further concluded that very marked grain refinement results from a combination of the two mechanisms. Since  $TiC$  was found present in aluminum alloys refined by the addition of titanium, it was identified as the nucleating agent. In the case

F. A. CROSSLEY, Junior Member AIME, is Head, Dept. of Foundry Engineering, Tennessee Agricultural and Industrial State College, Nashville, Tenn., and L. F. MONDOLFO, Member AIME, is Professor of Metallurgical Engineering, Illinois Institute of Technology, Chicago.

Discussion on this paper, TP 3179E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, March 14, 1951; revision, Sept. 4, 1951. New York Meeting, February 1952.

This paper represents part of a thesis by F. A. Crossley submitted in partial fulfillment of requirements for the degree of Doctor of Philosophy in Metallurgical Engineering to the Illinois Institute of Technology.

of the other refiners the identification of the nuclei as carbides was based on indirect evidence.

### Experimental Technique

The metals used in this investigation were high purity aluminum (99.90 pct) and other metals (at least 99 pct). In the experimental melts the alloying elements were so diluted that any impurity introduced by them was negligible.

The master alloys were prepared in zircon crucibles using an induction furnace, and the experimental melts were made in alumina crucibles at the start, but the less expensive clay crucibles, coated with sodium aluminate to prevent contamination, were later used for most of the investigation. Graphite crucibles were used for the alloys to which carbon was to be added. The experimental melts were made in electric resistance furnaces. For fluxing the alloys and wetting of the addition elements, Dow Chemical No. 230 was used. Argon gas of commercial purity, containing small amounts of oxygen and nitrogen, was introduced in some melts through alumina tubes.

The experimental melts were prepared by adding the required amount of master alloy to molten aluminum. When the melt reached a temperature 100°C above the liquidus it was stirred for a few minutes and then allowed to cool in the furnace. The rate of cooling was determined to be 6° to 7°C per min.

Fig. 3—Al-Ti equilibrium diagram and plot of grain size vs. composition of melt, series 7.

Fig. 4—Al-W equilibrium diagram and plot of grain size vs. composition of melt, series 5.

Five series of alloys were run this way, one for each of the alloying elements. Another series of Al-Ti alloys was treated with argon at the maximum temperature. The argon gas was bubbled through the melt for 30 sec, then the alloys were furnace cooled as usual. A third series of Al-Ti alloys was run in graphite crucibles, using the same technique as for the alloys discussed before. In addition three more melts were made in graphite crucibles using special techniques to increase the amount of carbon in the alloys. One melt containing 0.32 pct Ti was held at 850°C (approximately 100°C above the liquidus temperature) for 30 min. During this time aluminum carbide was stirred into it. This was followed by furnace cooling. The second melt, also containing 0.32 pct Ti, was treated in a similar way, but

graphite, instead of carbide, was stirred into it. The third melt, containing 0.50 pct Ti, was held at  $900^\circ\text{C}$  for  $2\frac{1}{2}$  hr in a graphite crucible, stirred thoroughly, and then furnace cooled.

The solidified specimens from all these melts had the approximate size and shape shown in Fig. 1.

Some of the grindings that resulted when the specimens were cut and faced were analyzed by wet methods. In most alloys the difference between these analyses and the nominal ones was within the error of analysis (approximately 0.01 pct). The zirconium-bearing alloys, however, showed large losses of zirconium, and for this reason all of them were analyzed. The nominal compositions or, when available, the actual analyses are reported in col. 2, Table I.

After the melts had solidified and they were examined for grain size, other spot checks for composition were run. The grain size count was done in all specimens at the same distance from the bottom, along a horizontal line. Drillings were then taken along this line with a  $\frac{1}{8}$ -in. drill and analyzed. This was done because segregation of primary crystals was evident in some alloys. These analyses revealed that segregation was appreciable only in the alloys

with an alloying content above 1 pct. For the other alloys the difference between the nominal analysis and the analysis of the zone where the grain determination was done was within the error of analysis. These analyses are reported in col. 3 of Table I.

The ingots were sectioned vertically at the center, and the grain size of the specimens was measured by counting the grains intercepted by a line running horizontally on the polished face 0.3 in. from the bottom. Great care was taken to position this line exactly on the specimens, since variations of grain size were found from top to bottom of the melts, as shown in Fig. 1.

## Results and Discussion

In Figs. 2 to 7 are shown the effects of increasing additions of the elements on the grain size, as related to the equilibrium diagrams. Dashed lines have been used when the data are uncertain.

In the Al-Fe alloys, as the iron content was increased, the grain size decreased slightly with the first additions of iron, remained fairly constant over a wide range, well past the eutectic point, and then slowly increased. At the lower concentrations the other alloys behaved similarly, but when the composition was reached, at which the peritectic reaction occurred, a marked grain refinement appeared; and there was a sharp change in the slope of the grain size curve. With increasing additions beyond the start of the peritectic reaction, the grain refinement reached a maximum and then decreased.

At the point where the first change in slope of the grain size curve took place, primary crystals of intermetallic compound were formed. However, the presence of primary crystals per se could not be the cause of grain refinement, since in the hypereutectic Al-Fe alloys the same effect could not be noticed. Thus, the evidence points to the peritectic reaction as the cause of the grain refinement.

The above supposition found good confirmation from the microexamination. As shown in Figs. 8 to 10, the primary crystals of intermetallic compound were found inside the crystal, and the dendrites of aluminum solid solution appeared to center on them. Some of the dendrites did not show primary crystals. However, this can be explained by assuming that either the primary crystal was not in the plane of

Fig. 11—Shape of primary crystals of  $\text{TiAl}_3$  when rapidly frozen 1.3 pct Ti poured in water. Etched with 1 pct HF. X700.

Fig. 12—Effect of carbon additions on the grain size of Al-Ti alloys.

Fig. 13—Effect of treating with argon gas on the grain size of Al-Ti alloys.

the section, or the peritectic reaction was completed and the primary crystal was consumed. Fig. 10 shows the same type of distribution of primary crystals and in addition shows that, when the number of primary crystals was sufficient, practically every grain surrounded a primary crystal. The micrographs shown are all of alloys with amounts of alloying element well above the beginning of the peritectic reaction. This was necessarily so, because with lower contents the primary crystals were completely consumed and disappeared. This explains the relatively coarse grain size in the micrographs.

The same type of evidence for nucleation was also found in the other systems (with the exception of the Al-Fe), although in some cases the evidence was not as clear as in the examples shown. In the Al-Zr and Al-W alloys it was not possible to develop the dendritic structure well enough to photograph it, although evidence of nucleation around the primary crystals was visible when the alloys were strongly over-etched.

Extensive microexamination was conducted to determine if fragmentation of the primary crystals played a significant role in the refinement. It was found that the intermetallic compounds formed by the grain refiners investigated tended to have a platelike (needles in section) structure, rather than the dendritic structure deemed necessary for fragmentation by Asato et al. Even very rapid cooling did not appreciably change the form of the primary crystals, as evidenced by Fig. 11. Cracking of the primary crystals was sometimes observed (Fig. 8) and there was some evidence that occasionally the pieces of a primary crystal, when broken, nucleated two or more grains. However, this phenomenon was found in very few cases and did not seem to play an important part in the grain refinement.

In Fig. 12 are plotted the results of experiments run in the presence of carbon. Three sets of results are plotted: 1—melts in which the introduction of carbon was carefully avoided (series 7); 2—melts in which some carbon was absorbed from the graphite crucibles (series 2); and 3—melts in which an effort

was made to introduce large amounts of carbon (melts 2-1c, 2-2c, 2-3c). The grain size of the alloys in which no peritectic reaction occurred was not appreciably affected by the addition of carbon. In the alloys undergoing the peritectic reaction the effect of carbon additions was very pronounced and the grain refining effect was greatly reduced, and even disappeared when sufficient carbon was present. These results are in direct opposition to Cibula's statement that TiC is the agent responsible for grain refinement, because if this were true, grain refinement should have increased with increasing carbon content. Instead, the suggestion is further substantiated that the peritectic reaction of  $\text{TiAl}_3$  with the liquid was responsible for the grain refinement. The addition of carbon, by tying up the titanium as TiC, prevented the formation of  $\text{TiAl}_3$ .

Hollomon and coworkers<sup>11</sup> and others<sup>12-16</sup> have demonstrated that solid impurities in a melt can act as

Fig. 14—Effect of number of primary crystals on grain size. At the bottom large amount of fine primary crystals, above few coarse primary crystals. Etched with 1 pct HF-1.5 pct Ti, slow cooled in furnace. X5.

centers for crystallization. Any treatment that reduces the amount of the solid impurities must result in a coarsening of the grain. This is clearly shown in Fig. 13. The alloys in which argon treatment had removed impurities solid above the liquidus temperature showed a much coarser grain than the non-treated alloys. However, the shape of the grain size curve was the same, thus indicating that, although the number of  $\text{TiAl}_3$  particles was reduced, their effect as nucleating agents was not lost. The dependence of the grain size on the number of primary crystals is also shown in Fig. 14. Because of gravity segregation a large number of primary crystals were concentrated in the bottom layer and the grain size there was very small, the layer above it contained only a few large primary crystals, and the grain size was coarse.

### Conclusions

Grain refinement in aluminum alloys by the addition of titanium, zirconium, molybdenum, chromium, and tungsten is associated with the peritectic reaction. The primary crystals of intermetallic compound which form, react with the liquid and become sheathed with a solid having the crystal structure of the phase that is going to be formed from the liquid. These solid particles act as nuclei for the crystallization of the melt, thus eliminating the necessity for undercooling to provide spontaneous nucleation.

In the case of the above elements, fragmentation of the primary crystals during peritectic reaction was not observed to an appreciable extent and consequently does not seem to play an important part in the grain refinement.

The final grain size appears to be mainly dependent on the number of primary crystals that form, and any factor which affects the number of these crystals will alter the grain size.

The addition of carbon to Al-Ti alloys reduces the grain refining effect, and the effect of the grain refining agent is lost if sufficient carbon is added.

Some grain refinement can be obtained by additions of the above elements in amounts insufficient to produce the peritectic reaction, or by the addition of other elements, but the effect is not as pronounced as when the peritectic reaction occurs.

### Summary

The mechanism of grain refinement by the addition of chromium, titanium, tungsten, molybdenum, zirconium, and iron was investigated. The first five elements, when present in sufficient amounts, formed

primary crystals which reacted peritectically with the liquid. The resulting solid particles acted to nucleate the solidification of the remaining liquid. This extra source of nucleation produced decided grain refinement in many cases. It was found that lesser amounts of the five elements and even large additions of iron only slightly reduced the grain size. No evidence of nucleation by primary crystals of  $\text{FeAl}_3$  was found. Upon these findings it was concluded that the peritectic reaction was necessary for decided grain refinement. No evidence was found that fragmentation of the primary crystals was of importance in producing the grain refinement, as reported by Asato et al. Removal of solid impurities and additions of carbon to the melt were found to decrease decidedly the grain refining effect.

### Acknowledgment

The authors gratefully acknowledge their indebtedness to the Apex Smelting Co. and to the Reynolds Metals Co. for the chemical analyses, to the Aluminum Co. of America for the high purity aluminum, to the Titanium Manufacturing Co. for the titanium and zirconium of high purity and the zircon crucibles. The authors also wish to thank the members of the staff and the students of the Department of Metallurgical Engineering of Illinois Institute of Technology, whose aid and suggestions were helpful in the course of this research.

### Technical Note

## Surface Effect in the Cleavage of Zinc Monocrystals

by John J. Gilman

**S**URFACE effects in the brittle fracture of materials such as glass and in the plastic slip of zinc and cadmium crystals are well known.<sup>1</sup> Recently, another surface effect has been found for zinc monocrystals. It has been observed that certain normally ductile zinc monocrystals become ex-

tremely brittle when their surface is coated with a layer of oxide or copper plate.

J. J. GILMAN, Junior Member AIME, is associated with the School of Mines, Columbia University, New York.  
TN 90E. Manuscript, Aug. 23, 1951.

This phenomenon was first observed in a triangular zinc crystal which had been grown in a graphite mold surrounded by an atmosphere of air. The lowering rate during growth was 1 in. per hr and the temperature gradient in the furnace at the melting point was approximately 24°C per in. The raw zinc was chemically pure (99.999+ pct Zn). This crystal had a fairly thick (perhaps ½ mil thick) porous oxide coating as grown. Although its orientation was favorable ( $\chi$ , 46°;  $\lambda$ , 48°;  $\theta$ , 47°) for ductile bending, it cleaved without prior plastic deformation when loaded in bending. The load required for cleavage was appreciably greater when the maximum tensile stress was at the apex of the triangular cross-section nearest the slip direction than it was when the base of the triangle was in tension. The cleavages were good basal cleavages. However, the crystal was "optically mosaic," see Fig. 1 and Ref. 2; that is, the cleaved basal planes were not absolutely plane. They consisted of two or more very slightly disoriented regions as shown for a typical cleavage in Fig. 1.

In order to render this extremely brittle crystal very ductile it was only necessary to etch away the oxide layer. This was accomplished by a 10 min etch in 15 pct HCl. After this treatment the crystal could be bent completely around a 2 mm diam rod without cleavage.

A very similar effect was observed for two copper-plated crystals. These crystals were also triangular and of the same size (base of triangle is 0.210 in.), but they were grown in molds sealed inside evacuated pyrex tubes. They had the following orientation angles: crystal A— $\chi$ , 50°;  $\lambda$ , 50°;  $\theta$ , 49°; and crystal B— $\chi$ , 56°;  $\lambda$ , 56°;  $\theta$ , 63°.

Crystal A was cleaned with dilute HCl and then plated with a thin coating of copper for half of its length (7 in.). This copper coating was very fine grained and approximately 2200Å thick. When the crystal was loaded in tension the clean portion began to deform plastically at a resolved shear-stress of 32 g per sq mm, while the plated portion began to deform when the resolved shear stress reached 52 g per sq mm. Further loading caused additional plastic deformation until the plated portion of the crystal cleaved when the resolved normal stress was approximately 93 g per sq mm and the elongation in the plated portion was 2.5 pct. When the crystal was loaded in bending several days later the two portions of the crystal exhibited markedly different amounts of ductility. The amounts of bending which each portion could stand is shown in Fig. 2. The basal cleavages shown in Fig. 2 were optically mosaic just as those of the oxidized crystal.

Crystal B was cleaned with HCl and then plated with a film of copper approximately 5000Å thick. This crystal was very ductile when loaded in bending prior to the plating treatment. When it was loaded in bending a few hours after it had been plated it was very brittle. It had less ductility than crystal A after it had been plated. After the plate had been etched off with 25 pct HCl, the crystal was again ductile. In this case, also, when the basal cleavages were examined they were found to be optically mosaic.

These effects have not been found in all zinc crystals and, therefore, are tentatively associated

Fig. 1—Optically mosaic basal cleavage of a brittle triangular zinc crystal.

Fig. 2—Showing the difference in ductility between the copper-plated portion of crystal A and the clean portion. On the left is the plated half of the crystal.

with optically mosaic ones. However, the extreme change in ductility is produced by a change in the surface of the same crystal and to this extent is reproducible.

The phenomenological explanation of the effect might be as follows: The oxide or copper coating is very fine grained and therefore has little ductility. When the crystal is loaded in bending, brittle failure of the film creates a rift at the surface which starts cleavage along the basal plane of the zinc. Basal cleavage then propagates readily even though the crystal is ductile, just as it does if a razor blade is used as a wedge along a basal plane of a ductile zinc crystal. Another possible explanation is that the oxide coating or the copper plating inhibits slip so strongly that the critical normal stress for cleavage is reached before much slip can occur. The reason why some crystals do not behave in this way is not known. It may be that the surface effect is more subtle than those which are outlined above, but the present observations leave this as an open question.

# Constitution of Titanium-Aluminum Alloys

by H. R. Ogden, D. J. Maykuth, W. L. Finlay, and R. I. Jaffee

Aluminum has been found to be soluble in  $\alpha$  titanium to about 26 pct, and to raise the temperature range of transformation from  $\alpha$  to  $\beta$ . Two intermediate phases exist in the system, a new face-centered tetragonal phase, designated as  $\gamma$ , which occurs between 34 and 46 pct Al, and  $\text{TiAl}_3$ . Metallographic and X-ray diffraction data were used to determine the diagram.

**A**LUMINUM is one of the useful alloying additions for titanium-base alloys. It is an important constituent in two commercial alloys released in 1950, one containing 4 pct Al and 4 pct Mn, and the other containing 3 pct Al and 5 pct Cr as the metallic alloy content. It is probable that, in the future, other titanium alloys containing aluminum will be released. In the course of alloy development work, some of the features of the constitution of titanium-rich Ti-Al alloys have been developed. These are described in the present paper.

The only available information on the Ti-Al system concerns the aluminum-rich end of the diagram. In summarizing the early work, Hansen<sup>1</sup> indicated that there is little solubility of titanium in aluminum, and that a two-phase region exists up to the intermediate compound,  $\text{TiAl}_3$  (37.2 wt pct Ti), which has a congruent melting point at 1355°C. Fink<sup>2</sup> has reported that a peritectic reaction occurs at 665°C between the melt and  $\text{TiAl}_3$  to form the terminal solid solution of titanium in aluminum. The solubility of titanium in aluminum has been established at 0.24 pct at 510°C and is estimated to be between 1 and 1.5 pct at the peritectic temperature.

No information has been published on the diagram

above  $\text{TiAl}_3$ , other than a statement<sup>3</sup> that aluminum raises the  $\alpha$  to  $\beta$  transformation temperature of titanium.

## Materials and Preparation of Alloys

Iodide-type titanium and high-purity aluminum were used in this investigation. Typical analyses of these materials are given in Table I. Alloys were prepared by arc melting on a water-cooled copper hearth, using the techniques described previously for contamination-free melting.<sup>4</sup> Weight losses during melting were very low, ranging from 0 to 0.02 g in a 10 to 15 g charge, indicating that little or no loss of aluminum occurred during melting. This permitted the use of nominal compositions for these alloys.

Alloy ingots containing from 0 to 7.5 pct Al were rolled in air at 850°C to 0.040 in. sheet. Alloys containing from 7.5 to 16 pct Al could only be rolled about 25 pct reduction at temperatures up to and including 1200°C. Alloys containing above 16 pct Al

Fig. 1—Tentative diagram of the Ti-Al system.

were evaluated using cast ingots. The fabricated alloys were annealed for 3½ hr at 850°C in a vacuum of  $1 \times 10^{-4}$  mm Hg pressure before testing. After casting, the high aluminum alloys were given an homogenization anneal of 24 to 48 hr at 1000° to 1100°C before evaluation.

### Methods of Investigation

Alloy constitution was determined mainly by metallographic methods, supplemented by X-ray diffraction. For a few alloys, transition temperatures were checked using the inverse-rate method of thermal analysis. Melting temperatures of the titanium-rich alloys were obtained by observing the melting of an ingot with a hole drilled in it.

Heat treatments were done in a resistance furnace using an atmosphere of gettered argon. Temperature control was maintained at  $\pm 3^\circ\text{C}$  during the heat treatment. Iodide-titanium control samples showed no hardness increase after several hours at 1050°C, which indicated no contamination during heat treatment. The specimens were quenched into water from the heat-treatment temperature.

The metallographic specimens were mounted in bakelite, ground through 600X paper, and given a final polish with either diamond paste or jeweler's rouge on a wool lap. Etching was done with an aqueous solution of 3 pct  $\text{HNO}_3$ , 1½ pct  $\text{HF}$ .

All X-ray diffraction work was done on powder

Fig. 2—Section of Ti-Al diagram showing data points.

samples. To avoid contamination during heat treatment, the alloy filings were kept in a hole drilled into a short length of as-deposited iodide-titanium rod, and capped with a titanium plug. This, in turn, was encapsulated in vacuum in Vycor. After heat treatment for the desired time and temperature, the Vycor capsule was quenched and broken under water.

The X-ray diffraction patterns on the powders were obtained using cobalt K radiation in a 57 mm Debye camera of the Buerger type with a Straumaius setting. An aluminum filter was inserted between the sample and the film to absorb scattered radiation. The lattice constants were calculated by the method of simultaneous equations from the quadratic form of the Bragg equation using the angular position of the (12.1) and the (11.4)  $\text{K}\alpha$  doublets, and, in alloys containing up to 7.5 pct Al, the (12.3)  $\text{K}\beta$  reflection.

In the melting point work, ingot samples were used which had a ⅛ in. hole drilled in them. These were supported by a molybdenum lining in a beryllia crucible and heated by induction in a vacuum furnace, using a graphite sleeve inductor. The temperature of the hole was observed continually with

Fig. 3—Effect of aluminum on the transformation temperature of titanium.

an optical pyrometer, and the temperature at which the hole filled with molten metal was taken as the liquidus temperature. Solidus temperatures could be approximated by observing the temperature at which the edges of the hole started to round off.

### Constitution Diagram

A tentative diagram of the Ti-Al system is given in Fig. 1. The solid lines indicate the phase boundaries that have been established by this investigation between 0 and 50 pct Al and by others<sup>1, 2</sup> between 50 and 100 pct Al. Dashed lines indicate the probable equilibria in the areas not covered in this investigation, based on extrapolation of known data and pertinent observations discussed later in this paper. The solid equilibria section of the diagram covered by the present work is shown in Fig. 2, where data points indicate the results of microscopic examination. Fig. 3 shows the effect of aluminum on the transformation temperature of titanium between 0 and 7.5 pct Al in more detail. Aluminum is seen to cause a marked increase in the temperature range of the  $\alpha$ - $\beta$  transformation.

Thermal analysis produced an arrest at 888°C for

unalloyed titanium, at 964°C for a Ti-5 pct Al alloy, and at 1051°C for a Ti-8 pct Al alloy. These data confirmed the results of the metallographic work.

The melting point data obtained are given in Table II. The melting point obtained for pure titanium is considerably below the 1725°C melting point observed by De Boer.<sup>5</sup> This may have been the result of contamination from the carbon inductor. The melting point data obtained on the Ti-Al alloys fit better with 1725°C for the melting point of titanium. Also, they indicate a very slight decrease in melting point imparted by aluminum up to 20 pct Al. Above 20 pct Al, the melting point drops off much more rapidly.

Table II. Melting Point Data

| Wt, Pct Al | Incipient Melting, °C | Completely Molten, °C |
|------------|-----------------------|-----------------------|
| 0          | 1690                  | 1690                  |
| 5          | 1710                  | 1710                  |
| 10         | 1700                  | 1700                  |
| 20         | 1670                  | 1690                  |
| 30         |                       | 1600                  |
| 40         |                       | 1480                  |

The limit of solubility of aluminum in  $\alpha$  titanium has been established at about 26 pct between room temperature and 1100°C. The raising of the  $\alpha$ - $\beta$  transformation range by aluminum results in an extensive, but restricted,  $\beta$  field. With more than 26 pct Al, a new phase appears, and two-phase structures are found up to about 33 pct Al. Between 33 and 46 pct Al, a single-phase region occurs which has a face-centered tetragonal structure. This has been designated as the  $\gamma$  phase. The composition corresponding to TiAl<sub>3</sub>, 36 wt pct Al, is located within the  $\gamma$ -phase field. Above 46 pct Al, the TiAl<sub>3</sub> phase appears, which indicates that the two-phase region of  $\gamma$ -plus-TiAl<sub>3</sub> extends up to the composition limits of TiAl<sub>3</sub>.

The section of the diagram above 1050°C has been sketched in to show the probable equilibria at the higher temperatures. Since the melting point of titanium was found to be depressed only slightly by initial additions of aluminum, the extrapolation of the  $\alpha$  and  $\beta$  solvus lines would indicate a peritectic reaction occurring at a high temperature, at about 25 pct Al. The marked lowering of the melting point for the 30 and 40 pct Al alloys indicates that there

As-cast plus 48 hr at 1100°C.  $\gamma$  and TiAls.

is a second peritectic reaction between  $\alpha$  and liquid to form the  $\gamma$  phase. The melting point of the Ti-40 pct Al alloy has been established at about 1480°C, which is probably fairly close to the peritectic temperature. The increase in solubility of aluminum in  $\alpha$  titanium at the  $\gamma$  peritectic temperature has been based on the microstructure of the  $\alpha$ -plus- $\gamma$  alloys, wherein an  $\alpha$  decomposition product is obtained.

### Microstructures

The microstructures of Ti-Al alloys at low aluminum contents are similar to those of titanium. Alloys rolled and annealed at temperatures within the  $\alpha$  field have equiaxed  $\alpha$  grains similar to those found in high purity titanium given the same treatment. A typical structure of this type is shown in Fig. 4 for a Ti-5 pct Al alloy annealed at 850°C. Quenching the alloys from the  $\beta$  field results in a transformation structure of large, serrated Widmanstätten plates, very similar to that found with iodide titanium. This structure is shown in Fig. 5. The microstructure of alloys quenched from the  $\alpha$ -plus- $\beta$  field consists of a mixture of equiaxed  $\alpha$  grains and serrated Widmanstätten plates. This structure is dif-

ficult to interpret because of the similarity between the two types of grains. A typical structure is shown in Fig. 6 for a Ti-5 pct Al alloy quenched from 975°C. In the composition range of 8 to 16 pct Al, where the alloys had been rolled about 25 pct reduction at 1000°C, annealing for 24 hr at 1000°C produced an equiaxed  $\alpha$  structure, as shown in Fig. 7. Alloys containing above 16 pct Al, which could not be fabricated, were examined after an homogenizing anneal of 24 hr at 1000°C. At 20 pct Al, Fig. 8, the structure consists of large Widmanstätten plates, indicative of a  $\beta$  to  $\alpha$  transformation structure. These plates probably existed in the as-cast alloy and were not overcome by the homogenizing anneal. Several cracks can be seen in the structures of the 16 and 20 pct Al alloys, illustrative of the inherent brittleness of the high aluminum-content  $\alpha$  range. At 25 and 26 pct Al, Fig. 9, equiaxed  $\alpha$  grain structures were obtained which showed no evidence of a transformation from the  $\beta$  phase. These data indicate that the solubility limit of aluminum in  $\beta$  titanium lies between 20 and 25 pct Al, probably quite close to 20 pct.

In the  $\alpha$ -plus- $\gamma$  field, the alloys have a banded

Fig. 16—Ti-72 pct Al alloy. X50.  
As-cast structure.  $TiAl_3$  and Al.

structure, suggesting that the  $\alpha$  phase has precipitated the  $\gamma$  phase on cooling. This is shown in the Ti-28 pct Al and Ti-30 pct Al alloys, Figs. 10 and 11, where the entire grain is banded. This indicates that the maximum solubility of aluminum in the  $\alpha$  phase is at least 30 pct at the  $\gamma$  peritectic temperature. At 32 pct Al, the banded structure still exists, but separate  $\gamma$  grains are beginning to appear. This structure is shown in Fig. 12.

Figs. 13 and 14 show microstructures of the  $\gamma$ -phase alloys after a homogenization treatment of 48 hr at 1100°C. The Ti-34 pct Al alloy has an equiaxed grain structure rather similar to that found in face-centered cubic metals. This structure persisted to 40 pct Al. From 42 through 46 pct Al, somewhat different structures, shown for the Ti-46 pct Al alloy in Fig. 11, were obtained. The fine structure shown there is not believed to be grain-boundary precipitation, but is more likely the result of coring derived from a long freezing range. If it is assumed that the composition of the  $\gamma$  phase at the peritectic temperature occurs at about 40 pct Al, then the differences in microstructure are readily understandable. A longer freezing range on the aluminum-rich side of this point could account for the heavily cored structure of these alloys.

The microstructure of a  $\gamma$ -plus- $TiAl_3$  alloy is shown in Fig. 15, and that of a  $TiAl_3$ -plus-aluminum alloy is shown in Fig. 16. The Ti-50 pct Al alloy consists of needles of  $TiAl_3$  in a matrix of  $\gamma$  phase, while the Ti-72 pct Al alloy consists of dendrites of  $TiAl_3$  with aluminum present as the dendritic filler. The  $TiAl_3$  phase has been identified in both of these alloys by X-ray diffraction using lattice spacings reported by Fink, Van Horn, and Budge.<sup>6</sup>

### X-Ray Diffraction

The lattice-constant curves showing the effect of aluminum on the lattice constants of titanium are given in Fig. 17. To obtain these data, powder samples of alloys containing up to 7.5 wt pct Al were heat treated for 1 hr at 800°C and alloys containing 10 to 25 wt pct Al were heat treated 20 min at 850°C. The lattice constant  $a_0$  decreases almost linearly with increasing aluminum content. However, the  $c_0$  curve shows a hump at low aluminum contents, which may be indicative of oxygen and/or nitrogen contamination in the powder samples. Clark<sup>7</sup> has shown that both oxygen and nitrogen cause an increase in the

Fig. 17—Effect of aluminum on the lattice constants of titanium.

$c_0$  constant of titanium, but they do not significantly affect the  $a_0$  constant. However, even assuming some contamination of the low aluminum-content alloys, the  $c_0$  values in this range seem much higher than would be expected. Using the actual values, the axial ratio  $c/a$  increases almost linearly, 1.591 at 0 pct Al to 1.604 at 20 atomic pct Al. Above 20 atomic pct Al, the axial ratio remains constant at 1.604.

It was also found that the annealing treatment given to powder samples had a direct bearing on the lattice constants obtained. Filings of alloys containing 10 to 25 wt pct Al annealed in vacuum in the titanium-block holder for 24 hr at 1000°C had lattice constants corresponding to about 2.5 wt pct Al, and gave very diffuse patterns. This was probably caused by diffusion of the aluminum from the filings into the titanium capsule, or diffusion of titanium from the capsule into the filings. Similarly, powder samples of alloys containing 30, 35, and 40 wt pct Al, which had been identified microscopically as  $\alpha$ -plus- $\gamma$  and  $\gamma$ -phase alloys, had lattice constants of the  $\alpha$  phase corresponding to 2.5 pct Al with no  $\gamma$ -phase lines present when annealed 24 hr at 1100°C. These alloys were checked by X-ray diffraction examination of filings made from solid samples given the same annealing treatment. The patterns obtained were diffuse, because of the cold work present in the filings, but both the  $\gamma$  and  $\alpha$  phases could be identified in the 30 wt pct Al alloy and only the  $\gamma$  phase in the 35 and 40 wt pct alloys. Therefore, the technique of first homogenizing block samples of  $\alpha$ -plus- $\gamma$  and  $\gamma$ -phase alloys followed by low temperature annealing of the powder samples was adopted for these alloys.

Using the lattice-parameter curves in Fig. 17, an attempt was made to determine the effect of temperature on the solubility of aluminum in  $\alpha$  titanium.

Table III. Alpha Lattice Constants of a Ti-30 Pct Al Alloy Quenched from Various Temperatures

Fig. 18—Effect of carbon, oxygen, and nitrogen on the transformation range at the level of 5 pct Al.

Powder samples of a Ti-30 pct Al alloy were quenched from several temperatures, and lattice constants of the  $\alpha$  phase were determined. The lattice constants and corresponding aluminum solubilities at the various temperatures are given in Table III. The  $\alpha$  solubilities of aluminum calculated from the X-ray diffraction data are of the same order of magnitude but are 2 to 3 wt pct Al lower than the value determined microscopically. The lower solubilities are believed to be caused by the diffusion effect noted before. Therefore, it is considered that the metallographic observations on the terminal solubility of aluminum in  $\alpha$  titanium are more reliable than those using X-ray diffraction.

Diffraction patterns of  $\gamma$ -phase alloys (33 to 46 wt pct Al) were diffuse, and precision lattice constants could not be obtained. Filings for this work were taken from block samples homogenized for 48 hr at 1100°C and then given a short-time strain-relief anneal. The diffuse patterns may have been caused by either an insufficient homogenization treatment, or an insufficient strain-relief anneal. However, good patterns were obtained of the  $\gamma$  phase from alloys in the  $\alpha$ -plus- $\gamma$  and  $\gamma$ -plus  $\text{TiAl}_3$  fields, so that the lattice constants of the upper and lower limits were obtained. These are given in Table IV. The crystal structure has been established as face-centered tetragonal with an axial ratio  $c/a$  of 1.012 to 1.018. It is interesting to note that the lattice constants of the  $\gamma$  phase are very close to the lattice constant of aluminum, 4.0408Å.<sup>8</sup> It has also been established that the  $\gamma$  phase has an ordered structure, probably of the CuAu type with alternate layers of titanium and aluminum atoms. Superlattice lines were observed in all alloys containing from 30 to 50 wt pct Al, and, although precision lattice constants could not be determined for  $\gamma$ -phase alloys, the superlattice lines were still discernible. Quenching alloys containing 35 to 40 wt pct Al from temperatures up to 1050°C did not overcome the ordered structure, indicating either that no order-disorder transformation exists at least up to 1050°C, or that it cannot be suppressed by quenching.

### Effects of Carbon, Oxygen, and Nitrogen

Because carbon, oxygen, and nitrogen are the major impurities present in commercial grades of

Table IV. Lattice Constants of Gamma Phase

| Aluminum Content |            | Lattice Constants, Å |        | Other Phases Present |
|------------------|------------|----------------------|--------|----------------------|
| Wt Pct           | Atomic Pct | $a$                  | $c$    |                      |
| 30               | 43.25      | 4.0155               | 4.0625 | $\alpha$             |
| 50               | 64         | 3.976                | 4.049  | $\text{TiAl}_3$      |

titanium, it is important to know their effects in small quantities on the Ti-Al diagram. Fig. 18 shows the effect of carbon, oxygen, and nitrogen on the transformation range at the 5 pct Al level. All three of the interstitial additions raise the  $\alpha$  and  $\beta$  transus temperatures markedly, which is what might be expected from the previous data on the binary alloys of these elements with titanium.<sup>4</sup> In all three cases, the slopes of the  $\alpha$  and  $\beta$  transus lines have been estimated from the quantity of  $\beta$  present at temperatures within the  $\alpha$ - $\beta$  field. Precise determinations of the exact location of these lines have not been made.

### Summary

The titanium-rich portion of the Ti-Al diagram has been surveyed between room temperature and 1100°C. Very limited data were taken above 1100°C, and the diagram in this region has been sketched in chiefly to conform with melting point data and microstructural appearance of cast alloys. The main features of the diagram may be summarized as:

1—The solubility of aluminum in  $\alpha$  titanium is about 26 wt pct.

2—The temperature of  $\alpha$  to  $\beta$  transformation is increased by aluminum additions, resulting in a two-phase field where  $\beta$  solubilities are less than  $\alpha$  solubilities. This is the first documented case of a metallic  $\alpha$ -stabilizing addition for titanium.

3—A new phase designated as  $\gamma$  occurs between 34 and 46 pct Al. This phase has an ordered face-centered tetragonal structure with an axial ratio close to unity and with lattice constants very close to the lattice constant of aluminum.

4—Aluminum additions up to 20 pct do not appreciably lower the melting point of titanium. Above 20 pct Al, the melting point is markedly lowered.

In addition, the effects of small amounts of carbon, oxygen, and nitrogen on the transformation range of Ti-Al alloys have been surveyed.

### Acknowledgments

The authors are grateful to Rem-Cru Titanium, Inc., for permission to publish the results of this work which was done at Battelle Memorial Institute under their sponsorship. They also wish to thank B. W. Gonser, of Battelle, for valuable suggestions and discussion, which greatly aided the progress of the experimental work, and J. R. Doig, of Battelle, for the X-ray diffraction measurements reported in this paper.

# Model for Dendrite Growth Form in Metals and Alloys

by R. B. Pond and S. W. Kessler

Metal specimens were solidified through a measured thermal gradient so a free surface and the liquid-solid interface could be examined. A line structure was observed on the surface and a hexagonal structure on the interface. A model to explain these forms is proposed.

NUMEROUS observations of the dendrite form have been made both in nonmetallic and metallic systems. From these, extrapolations have been made as to the probable dendrite form in pure metals. Observations of the dendrite form in pure metals, nevertheless, have been scanty. In general, these observations have been made on the skeleton dendrite after the mother liquid has been drained from around it, and a mechanism of the formation of the dendrite has been postulated from this solid form. Recent investigations have been conducted in an endeavor to make a study of the formation of the dendrite in several pure metals and the effect of several variables on this mechanism and final form. For these investigations, an apparatus was designed and constructed as shown in Fig. 1. It consists of a talc block containing a half-cylindrical depression, the end of which terminates in the conical recess of a copper block having an external attachment for cooling. A heating coil extends the length of the mold just beneath the lower limits of the cavity. The entire cavity for holding metal is coated with a thin film of graphite. Six thermocouples are equally spaced in the cavity and under the graphite, and six microammeters indicate the temperatures at the particular thermocouple stations. Readings were taken of all meters at the same instant time measurements were taken by photographing the panel of microammeters and a stop watch which was started at the beginning of the run.

It was possible with this apparatus to solidify metals through a measured thermal gradient and to observe the progression of the liquid-solid interface with time by following the formation of the dendrite markings in the surface of the solid material. These

Discussion on this paper, TP 3159E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, June 21, 1951; revision, Sept. 14, 1951. New York Meeting, February 1952.

Fig. 3—Typical longitudinal and transverse striae witnessed in the surface of solidified pure tin. X50.

Fig. 4—Longitudinal striae delineating grain boundaries in pure tin. X50.

dendrite markings apparently were caused by the unequal and progressive growth of the dendrite segments and shrinkage of the liquid between these segments. When the residual liquid solidified, it was at this new level; and the dendrite was then marked out in relief. The dendrite in relief gave a frosted appearance to the solid as described by Turnbull and Cech,<sup>1</sup> while the liquid maintained a shiny mirror-like surface.

During the course of investigation, it was desired to observe the shape of the total liquid-solid interface in order to determine if the surface trace was characteristic of the total interface. This was accomplished by sucking the metal from the molten part of the bath at an extremely rapid rate after partial solidification. This process allowed another view of the dendrite form which was witnessed on the surface.

The dendrite form as witnessed on the surface was a stria or line structure aligned parallel, or roughly parallel, to the direction of growth (longitudinal striae), as well as a coarser line structure which was aligned roughly perpendicular to the longitudinal striae (transverse striae). The longitudinal striae were observed to be almost identical in form with that structure reported by Graf<sup>2</sup> as a layer-type structure, as can be seen in Fig. 2 by comparing his structure with the longitudinal striae. The transverse striae were not so easily witnessed and proved most difficult to photograph at the same time as the longitudinal striae. Fig. 3 shows the presence of both striae, and Fig. 4 shows the predominant appearance of the longitudinal striae and their delineation of the grain boundaries. The transverse striae in Fig. 4 appear only by faint light bands across the structure.

The longitudinal striae are of crystallographic origin, i.e., parallel within each grain but different from grain to grain. The transverse striae, on the other hand, often would be found to be parallel across all grains. It has been shown that this transverse striae is not a true dendrite marking however, but is a shrinkage mark. This is explained with reference to Fig. 5. If the original volume of material  $S + L$  is liquid and solidification proceeds from 1 to 5, the first volume of material to solidify at 1 will be

at the liquid level, A. As the rest of the material decreases in temperature, the liquid level drops to B; and as the volume of material 2 solidifies, it will be at level B. This process is repeated, thereby giving a step-like surface to the solid, S, which will show as striae when viewed from above. This model points to the fact that the transverse striae should be more prominent in portions of the specimens where the liquid-solid interface existed when the liquid solidified under the most rapid rate of cooling. This was found to be the case. Fig. 6 is a micrograph of polycrystalline pure tin which was solidified from a point source and shows the transverse marking as arcs emanating from this point. Since these marks have a definite curvature in each grain, they cannot be classed as crystallographic or dendritic markings.

The bled face showed a hexagonal network similar to the hexagonaloid structure shown by Buerger.<sup>3</sup> Fig. 7 indicates that the longitudinal striae is the impression of the tops of the hexagons in the surface. A higher magnification of this structure shows a characteristic array of almost perfect hexagons, cf. Fig. 8. Fig. 9 shows the hexagonaloid to be a three dimensional unit with a breastlike shape; consequently, the name mammiform is assigned to it since this is the noun form of the word given by Dana<sup>4</sup> to describe such imitative shapes. A check to determine if these forms represented different grains was made by examination under polarized light. Fig. 10 shows three grains, each containing mammiforms, the grain boundaries being mammiform boundaries, and shows the mammiform in any one grain to be consistent in orientation with the rest of the grain. The specimen was deformed to produce twin bands which can be seen crossing the mammiforms and terminating at

the grain boundaries. It is to be noted that this structure is not the same as the cellular structures reported by Bengough,<sup>7</sup> and referred to as a double ture, the formation of which is described by Desch.<sup>6</sup> The cells of these structures are individual grains. The observed structure is probably the same as that reported by Bengough,<sup>7</sup> and referred to as a double cellular network, as well as by Smialowski<sup>8</sup> and Buerger.<sup>8</sup>

In an attempt to explain the hexagonal shape of the rod of the dendritic structure, consider an array of identical cones situated on a plane so that the axes of the cones are perpendicular to the plane, and are in a close-packed arrangement. If the cones are made sufficiently large so that their sides will everywhere intersect the sides of neighboring cones, these intersections will describe a net of hexagons,

Fig. 11—Development of array of hexagons by the intersection of cone bases.

Fig. 12—Sharp nosed pentagons developed by omitting one cone from the array.

Fig. 13—Square nosed pentagons developed by omitting two cones from the array.

cf. Fig. 11. It should be noted in Fig. 8 that there are other than six-sided figures. Using the model shown in Fig. 11, the misshapen figures can be explained by omitting a selected nucleus from the structure. Fig. 12 illustrates sharp-nosed pentagons obtained by omitting one nucleus, and Fig. 13 indicates square-nosed pentagons obtained by omission of two nuclei. Mammiforms were also observed where no great uniformity of shape existed, as in Fig. 14. Such nonuniform shapes can be constructed by omission of a sufficient number of selected nuclei.

Two major explanations are necessary relative to the inherent hexagonal shape of the rods. One, by what mechanism is the hexagonal close-packed

site selected for growth of the mammiforms; and two, why the particular shape of the mammiform? In an endeavor to answer the first question reference is made to Fig. 15.

The assumption is made that the block of material XYZ is solid material which has been solidified from the melt, and in which the face X represents the liquid-solid interface. The control gradient (or the gradient which controls the flow of heat from the liquid) along this block of material is expressed by line 1 and the solidification temperature of the material by line 2 on the temperature-distance curve adjacent to the block material. It will be noted that the temperature at the interface in this static condition is the solidification temperature of the metal. It is assumed, for the moment, that a block of material of mass A adjoins itself to the solid structure at A and transforms from a liquid into a solid. The latent heat of fusion of this mass A may be given up in three ways: 1—It may be conducted into the already solid material in accordance with the control gradient. 2—It may be diffused into the liquid in accordance with the temperature gradient in the liquid and the conductivity of the liquid. 3—It may be diffused in the surface X toward the boundaries of this face.

The thermal diffusivity of the metal in the surface X will determine the rate at which this heat is conducted away from point A. Consider, now, the heat dispersion in plane X at time  $t_1$ . For simplicity's sake, plane X is assumed to be thermally isotropic. It will be noted that the temperature at point A has been increased to  $A_1$ , as shown on the temperature-distance curve. If the mass A is to remain solid at the temperature  $A_1$ , either the small solid particle can be heated to  $A_1$  without melting, or  $A_1$  is the true solidification temperature and supercooling to the noted solidification temperature curve 2 is necessary to cause this initial solidification. The surface thermal gradient from point  $A_1$  is expressed by curve 3, and that closest point at which another mass of material can solidify is to be found on that loci of points represented by the surface gradient curve 3 crossing the solidification temperature curve 2. If it is now assumed that solidification occurs at some random point B of this loci of points, the latent

Fig. 14—Mammiforms in pure lead showing no extensive uniformity of shape. X50.

Fig. 15—Model for explaining mammiform site selection.

heat of fusion as noted before for A will be dispersed in a like manner; and a new loci of points will exist at which another mass of material can solidify. The possible positions of solidification determined by mass A are still imposed. The closest approach to A and B for this newest point will be at C, assuming that there is a proper balance of heat flow in the surface gradient and the control gradient. It is noticed that these A, B, and C points are in a close-packed arrangement, or that the angles between lines connecting these points are  $60^\circ$ . If, however, the balance of heat flow in the surface gradient and control gradient are not properly adjusted, point C may be removed away from points A and B or toward points A and B, thereby increasing or decreasing the closeness of packing.

If the solidification of masses A, B, and C should occur simultaneously and in a random fashion, so that any one mass is within the surface control gradient of another mass, then one of the masses must liquefy, since it will be above the solidification temperature. Consequently, the simultaneity of solidification is improbable unless the control gradient is sufficiently steep so that heat is removed from all masses at a rate such that the surface control gradient areas are very small. In this case, the masses may be solidified in random distribution. It should

Fig. 16—Model for explaining step-like solidification.

be noted that if the entire surface X is at the temperature of solidification, the deposition process may start from a multiplicity of points; and that although a close-packed array may exist in each area, the zones between these areas need not show a continuance of the order.

With this model for the selection of growth sites and the accompanying order of growth sites, there will be growth from these points in accordance with the growth vectors of the materials being solidified; i.e., the shape of the liquid-solid interface will be determined by the orientation of the crystal. However, this shape will be determined for every growth site, and consequently the liquid-solid interface for each site will approximate a cone projecting into the liquid if growth proceeds in a symmetry direction. Since the cone projected into the liquid will be entering areas of different temperature, or since a temperature gradient will exist down the axis of the cone, the shape of the cone cannot be expected to be extremely regular; and it will more nearly approach a mammiform structure. If this particular shape has grown out from the original plane X, a time will be reached when the bases of these mammiform figures will intersect. These intersections will form hexagons if the sites are in close-packed array. If the site C is removed from sites A

Fig. 17—Liquid-solid interface in pure tin which was not progressing when liquid was sucked off. Note absence of mammiforms. X500.

and B, as previously described, the shape of the intersection figures will be flattened hexagons. If a mass site is erased by being situated too close to another site, as described above, and yet exerts its influence on a third site prior to its eradication, then a vacant site may exist and the figures in this locale will be irregular pentagons, cf. Fig. 12. If the two sites are so erased, there will be two zones of irregular pentagons of different shapes. By making various sites disappear, almost any type figure can be made to exist, cf. Fig. 13, or if the sites are laid down at random as may occur if the control gradient is sufficiently steep, the figures will present themselves in many devious designs.

If growth from one site occurs before growth from other sites due to local differences in the control thermal gradient, then the size of the particular fig-

Fig. 18—Plot of average mammi-form size vs. solidification rate.

ure around this site will be relatively larger than its neighbor; but its geometry will remain unchanged. Conversely, a site which is delayed in its growth will have a relatively small size, and its geometry will be changed, cf. Fig. 12.

The transverse markings might be formed by the following mechanism: In Fig. 16, the original liquid level and the change in liquid level with time are represented at various positions of the bath; a series of mammi-forms A, B, C, etc., are growing; and at time  $t_1$ , the tip of mammi-form A has reached the liquid level and cannot propagate further into the liquid. The upper side of the form will continue to grow as long as there is metal available to feed it;

but it must be remembered that the liquid can flow off around the sides of the form, and consequently it will never be able to utilize the entire volume of metal available to it at  $t_1$ . The lower side of the form will also continue to grow until it grows out of the liquid so that at  $t_2$ , the tip of mammi-form B will have reached the liquid surface and mammi-form A will have terminated its growth in the profile shown. As the mammi-forms A, B, C, etc., continue to follow this procedure, the step-like shrinkage marking, previously described, is developed.

In the above models, the mammi-form is a growth form and would not be present if growth were not proceeding. The liquid-solid interface was held in one position for an hour by establishing a steady-state condition of heat flow and then all of the liquid was sucked off. No mammi-forms could be observed, as seen in Fig. 17. The background structure may be explained by the rapid solidification of that liquid metal which was wetting the solid metal and which could not be drawn off. Near the top edge of the specimen where drainage was more complete, an

Fig. 20—Model for explaining radial distribution of dendrite arms.

absence of this fine structure may be noted. This experiment was repeated with the exception that after the interface had been stopped for an hour growth was allowed to continue and the liquid immediately sucked off. The characteristic mammi-form structure was found.

By the above model, it was speculated that the steeper the control gradient in the solid, the greater would be the quantity of heat conducted into the solid per unit time and the smaller would be the available heat from the nucleus to be distributed in the liquid-solid interface. This means that the area influenced by a nucleating mass will be smaller or that the base area of the mammi-form would be smaller. Since the steepness of the control gradient was found to be roughly proportional to the rate of solidification, the average mammi-form sizes in specimens which had been solidified at various rates were determined and plotted vs. rate of solidification, Fig. 18. The envelope including the points shows the tendency for decrease in mammi-form size with an increase in growth rate as predicted from the proposed model.

Since the first observations and investigations of the mammi-form were made in specimens produced

Fig. 19—Model for explaining the tree-like dendrite of solid-solution alloys.

Fig. 21—Model for explaining alignment of mammiform sites along axis of original form.

as described above, it seemed necessary to check the existence of the mammiform when the metal was solidified in other ways. Polycrystalline metal masses were solidified in deep and shallow pots from the bottom, and in hollow tubes from the outside. In every instance, mammiforms were witnessed. The mammiforms were observed in all metals investigated, i.e., 99.997 pct pure Sn, 99.99+ pct pure Pb, 99.998 pct pure Bi, 99.999 pct pure In, 99.8+ pct pure Sb, and 99.997 pct pure Al.

An application of the proposed mammiform model in the case of the solid-solution alloys may be made in an endeavor to explain the mechanism of formation of the tree-like dendrite form. This is done by the imposition of a concentration gradient on the model, Fig. 19. The assumption is made that a relatively long mammiform A has grown onto the liquid-solid interface, that the temperature of the surface of this mammiform is (over microscopic segments) constant, and that with a given core temperature of the mammiform, the thermal gradient curve of this material is represented as curve Y. If a mass of concentration c-1 of solidification temperature T-1 deposits on site 1, the local temperature will be increased and the surface temperature gradient Z will be established so that the closest approach of the next mass c-1 to be deposited will be at 1-A. However, with reference to the concentration curve, it is seen that the concentration at point 1-A is c-2 and its solidification temperature T-2 and a solid mass of c-2 will not deposit at 1-A. However, at site 2 the solidification temperature T-2 has been reached and so c-2 will deposit there. The latent heat of fusion of c-2 will be given up and the process repeated. Since the temperature achieved by mass c-2 is less than that attained by c-1, the slope of the thermal gradient curve is less and so the site 3 where c-3 will deposit will be further from site 2 than site 2 is from site 1. This indicates that as growth proceeds, the concentration is changed, longer time is required for solidification because of the decrease in the temperature difference between the mammiform core temperature and the site temperature, and the cross arms should get farther and farther apart. This variation of distance between dendrite cross arms and speed of solidification as dependent on progression of growth was noted by Alexander and Rhines.<sup>9</sup> They also noted that the dendrite spacing in any one alloy system varied in the same manner as the ratio of the heat of fusion to the thermal diffusivity. In the proposed model, it is noted that the

Fig. 22—Schematic drawing of growth of the mammiform bases together to form webs.

slope of the surface control gradient curve Z, which determines the closeness of approach of the dendrite arms, will vary directly with the latent heat of fusion of the metal being deposited and inversely with the thermal diffusivity of the metal already deposited.

Reference to the probable temperature distribution curves Z around the mammiform, Fig. 20, indicates that the mammiform sites will be distributed 90° around the original mammiform. Fig. 21 shows how the mammiform sites are maintained in alignment along the length of the original form. After the masses B, C, and D, Fig. 21, have been deposited, it appears that E would be the next site to be occupied. However, the solute element has been diffusing toward E from both B and C, and point E will therefore be replete in the solute and have a lower solidification temperature than either G or F, so the points G and F will be selected as mammiform sites prior to E. As the mammiforms are continually formed in a line parallel to the original mammiform axis, their bases will grow together to form a web between the forms, Fig. 22. Cross arms on the cross arms can be developed in the same manner.

# A Survey of the Sulphur Problem Through The Various Operations in the Steel Plant

by T. E. Brower and B. M. Larsen

A perspective is presented of the steel plant sulphur distribution and elimination problem from coal to liquid steel ready for teeming, giving distributions of sulphur over a range of coke sulphur content, and some methods of sulphur control, in the blast furnace, external desulphurization between blast furnace and open hearth, distribution between fuel, slag, and metal, and methods and limitations of control of sulphur in the open hearth furnace.

AS a part of the 1951 AIME symposium on sulphur in steelmaking, it was thought that a discussion of the distribution of sulphur throughout the whole series of operations, from coal and ore to finished steel ingots, might have some value in giving a perspective on the whole problem. The following discussion is an attempt to present such an overall picture. The order is that of the actual plant operations, beginning with a very brief consideration of the coking process.

## Sulphur in Coal and Coke

Since by far the largest source of sulphur entering the steelmaking cycle is in the coal used to make coke for the blast furnace, it would seem reasonable to eliminate some of it, either from the coal, or the coke, or during the coking process. This has appeared impracticable up to the present, at least, for two main reasons: the low activity of the organic sulphur in either coal or coke, and because of price limitations involved in treating a low cost material such as coke.

A variable portion, usually  $\frac{1}{2}$  or less, of the sulphur is present in coal in the form of pyrites or similar compounds, and a large part of this sulphur may be removed in the coal washery. Most of the sulphur, however, is normally present as "organic" sulphur, intimately associated with the coal structure. Its distribution prevents any separation by mechanical means. Its low activity makes improbable any rapid chemical removal, although hydrogen will remove sulphur from both coal and coke. Thus, prolonged recirculation of coke oven gas in the coking process would tend to leave a smaller percentage of the total sulphur in the coke residue. Table I shows a typical distribution of sulphur from coal into products in the coking process. As the sulphur in the coal increases, the sulphur in the coke tends to increase in about the same proportion.

## Sulphur in the Blast Furnace

The best picture of the situation in the blast furnace is provided by a sulphur balance of raw materials entering, and of products leaving, the furnace. The difficulties in accurate weighing and sampling

of the variable solid materials entering this process, and the number of hours required for the raw materials to descend through the furnace under variable operating conditions, make it difficult to obtain an accurate balance. However, balances made over periods of weeks or months tend to average out some of these uncertainties.

Table II presents three typical sulphur balances similar to a number that the writers have calculated. In most of these the slag volume calculated from the sulphur balance is, in some instances more, and in other instances less, than the value corresponding to the best input and output balances of the other slag constituents (lime, silica, alumina, etc.). Probably the greatest source of error in these calculations is the sulphur content of the slag. Despite some possible inaccuracies the balances of Table II show rather definitely the following points:

1—That 87 to 95 pct of the total sulphur input is in the coke and 95 to 97 pct of the total sulphur output is in the slag. Also, that if any sulphur leaves the furnace with the gas it is relatively small, amounting to a possible 1 pct or less.

2—At the lower sulphur coke level of 0.86 pct the total amount of sulphur charged is 15 lb of sulphur per ton iron increasing to 26 lb per ton at the higher sulphur, intimately associated with the coal structure burdens containing sulphur-rich ores will the total sulphur burden fail to be nearly proportional to the content in the coke used.

3—The 7 to 9 pct of the total sulphur input from the limestone of furnaces B and C is due to the relatively high sulphur content of the stone, 0.226 and 0.265 pct, respectively. In the case of furnace A, the sulphur content of the limestone was only 0.06 pct which resulted in only 3 pct of the total sulphur input coming from this source.

It is rather interesting to compare the sulphur balances of a typical ferromanganese furnace with

the iron furnaces of Table II. Briefly the comparisons are as follows:

1—The percentage distribution of the items of the total sulphur input of both types of ore smelting is practically identical. That is, in the ferromanganese furnace 92 to 94 pct of the total sulphur is in the coke. Since the coke consumption of the ferromanganese furnace is approximately double that of the iron furnace, the total sulphur input is in the neighborhood of 40 to 45 lb sulphur per ton of ferromanganese for a 1.06 pct sulphur coke. (Compare with the iron furnace B of Table II which has a total input of 20.5 lb sulphur per ton iron.)

2—The output side of the sulphur balance of the two smelting processes is somewhat different. In the case of manganese smelting about 1 pct or less of the total sulphur is in the ferromanganese and approximately 80 to 85 pct is in the slag. The remaining 14 to 19 pct of the total sulphur was probably carried in the fine fume passing out the top of the furnace.

Since nearly all the sulphur burden in iron smelting can be attributed to the coke, the sulphur content of this raw material becomes of prime importance. In this country, coke with relatively low sulphur contents (0.70 to 1.00 pct) is becoming less common; we are having more and more to use cokes containing normally 1.20 and 1.30 pct, with periods of wide variations which occasionally reach values as high as 1.80 and 2.00 pct.

Sulphur distribution as determined by slag volume, calculated from other materials balances, is as follows:

|                                        |       |      |              |      |  |
|----------------------------------------|-------|------|--------------|------|--|
| CaO Balance                            |       |      |              |      |  |
| S in slag                              | 14.43 | 95.8 | 20.46        | 96.4 |  |
| S unaccounted for                      | 0.08  | 0.5  | -0.72        | 3.4  |  |

| Average pct S in<br>slag               |       | 1.74 | 2.01         | 2.49 |  |

Accordingly the sulphur problem of the blast furnace becomes one of distributing the total sulphur input between slag and iron so as to leave the iron with minimum sulphur content. Obviously this becomes more and more important as the total input increases due to the necessary usage of higher sulphur cokes.

With a process capable of leaving only about 3 pct of its total sulphur burden in the iron produced, desulphurization in the blast furnace is a problem only because the open hearth has such a limited capacity for sulphur removal. This is illustrated by the sulphur balances of the open hearth which will be discussed in more detail later. It is sufficient to mention that this small amount of sulphur remaining in the iron usually becomes, in turn, the largest single item of the sulphur input to the open hearth furnace. The slag-metal distribution follows the simple distribution law, not exactly perhaps, but closely enough to serve as a good guide in practice. That is, if the total sulphur input is doubled, the percentages in both slag and metal will be approximately twice as large. Since measured distribution ratios of sulphur in slag to sulphur in metal ( S )/[S ] vary from about 15 to 150, it would seem possible to compensate for a large increase in total sulphur burden, but there are limitations in practice:

Increasing the slag volume also increases the coke consumption, which, in addition to lowering production rate, causes the effect to be partially offset by the accompanying increase in total sulphur, since most of this comes from the coke. According to Steudel<sup>1</sup> each increment of 100 lb of slag requires approximately 50 lb of extra coke. This estimate agrees with that indicated by differences which existed in former years between northern and southern blast furnace practice. The lower iron content of southern ores gave approximately 2400 lb coke and 2400 lb slag per ton of iron. The richer iron ore of the north gave approximately 1800 lb coke and 1200 lb slag per ton of iron (both practices using about the same average blast temperature). Heat calculations based on Steudel's value of 50 lb extra coke indicate 275,000 Btu of extra input of heat are needed. Nearly half of this heat is consumed in melting the extra slag and burning the extra limestone, part of the remainder being available for processes in the shaft. It must be remembered that, unless the amount of sulphur held by this extra 100 lb slag is substantially greater than that carried in by the 50 lb coke, it is useless to increase slag volume as a means of obtaining low sulphur iron.

Ideally, the silicon content of basic iron should be only 0.7 pct or less, but nearly all low silicon practices show low sulphur ratios of around 15 to 40. These, in general, increase with silicon content, running as high as 100 to 140 at the 1.20 to 1.60 pct Si range. Of course, the increased silicon is in general accompanied by higher coke consumption, partially neutralizing the gain by an increased sulphur burden and lowered production rate.

Increased slag basicity as a very effective means for obtaining higher sulphur ratios also tends to involve a higher coke rate, larger flux requirements, and decreased production. Substitution of MgO for CaO, up to an optimum range of about 6 to 8 pct MgO, is one method which seems to involve no loss in production rate in most cases. If the increased basicity is achieved by the increase of only the CaO, the viscosity of the slag tends to be increased, which

Table III. Comparison of Practices and Sulphur Content of Iron with Increasing Sulphur Content of Coke

in turn requires a higher temperature to maintain a free running slag. However, if the MgO content is raised to about 6 to 8 pct of the final slag composition, the slag then becomes more fluid over a wide range of temperatures, as shown by McCaffery.<sup>2</sup> It was also shown in an earlier paper<sup>3</sup> that MgO in the range of 6 to 8 pct gave a good correlation with lower sulphur in the iron, with one molecule of MgO equal to or better than one molecule of CaO up to this limit.

Any trend toward lower coke consumption by higher blast temperature, or by factors such as sized ores and other charge materials which give greater regularity in operation, will of course favor sulphur removal with no penalty on production rate. Indeed, output rate is usually increased by such methods.

Better contact between metal and slag in the furnace would favor sulphur elimination, but this cannot be controlled by any method now known, except, perhaps, as shown by Steudel,<sup>1</sup> that longer retention of slag favors sulphur absorption, and this is severely limited by the space available below the tuyere level.

In spite of the fact that the theory is yet in dispute, it does appear that in practice a high manganese content in the iron favors increased sulphur ratios as indicated in the paper<sup>3</sup> mentioned above. Even though higher manganese practice does tend to decrease production rate to some small extent, this may be more than offset by the improved sulphur elimination.

As shown in Table III, however, in spite of limitations, the blast furnace can handle a considerable increase in sulphur burden with little or no increase in sulphur content in iron produced. In the cases listed here, the coke-sulphur contents range upward from 0.80 to 1.83 pct, yet all the averages for sulphur in iron remain within the limits of 0.029 to 0.042 pct. Certain points in this group of data may be worth noting, as follows:

Furnaces D and E both used relatively low sulphur coke, 0.80 and 0.95 pct, respectively. Both furnaces produced relatively low silicon iron, 0.71 and 0.83 pct, respectively. Both had approximately the same basicity ratio, 1.49 and 1.50, calculated as mols CaO + mols MgO/mols SiO<sub>2</sub>. However, this relatively low basicity ratio resulted in a moderately low sulphur distribution ratio of 44 for furnace D and 31 for furnace E. An interesting question raised by the comparison is why furnace D had on the average 13

units higher sulphur ratio and hence produced 0.006 pct lower sulphur iron (0.036 as compared to 0.042 for furnace E) despite a 0.12 pct lower silicon iron. The probable reason is the high manganese content of the iron, 2.36 pct, as compared to 0.31 pct for furnace E. It is possible that even greater desulphurization could have been obtained in the case of furnace D if the MgO had been 6 to 8 pct instead of 3.2 pct.

Furnaces F, G, and H had a charge of much higher sulphur coke, 1.30 to 1.42 pct. All three furnaces had comparable silicon contents in iron, 0.98 to 1.10 pct. The three furnaces also had nearly the same basicity, 1.60 to 1.64 mol basis. This basicity ratio is higher than that for the two preceding furnaces discussed above and results in higher sulphur distribution ratios, 59 to 82. Again it is interesting to find that furnace F which had the highest manganese content in the iron (2.85 pct) also had the highest sulphur ratio (82) and hence the lowest sulphur content of iron (0.029 pct) as compared with 0.037 and 0.042 pct for the other two furnaces.

Finally, the two separate weekly tabulations of furnace I represent a charge of still higher coke sulphur, 1.66 and 1.83 pct. Despite these high values the iron averaged relatively low in sulphur content (0.030 and 0.033 pct) with fairly high sulphur ratios (83 and 82). These values resulted mainly from the very high basicity, 1.7 mol basis. This is the highest basicity ratio of all the data listed in Table III. Also contributing to this high degree of desulphurization was the medium silicon (0.99 and 1.18 pct) and manganese (1.87 and 1.83 pct) contents together with a medium magnesia content of 5.0 and 5.8 pct. Probably even greater desulphurization would have resulted if the manganese in the iron had been higher.

In the paper by Kennedy and Thornton<sup>4</sup> a series of slag compositions were studied with respect to sulphur removal. In going from 0 to 100 pct dolomite flux charge it was found that the 35 pct dolomite, 65 limestone charge produced the maximum desulphurization. In Table I of their paper is shown the average results of 70 bessemer iron casts of this charge. Briefly the results can be summarized as follows:

The average sulphur distribution ratio was 101, which resulted in 0.018 pct sulphur in the iron. This high degree of desulphurization was achieved: 1—by a high basicity ratio (1.66 mol basis or 1.50 percentage basis) accompanied with 6.1 pct MgO in the

Fig. 1—Solubility of manganese and sulphur in hot metal as a function of temperature.

slag, and 2—with a high silicon content of the iron (1.53 pct) which indicates a high hearth temperature (2750°F average flush slag temperature). It is interesting to note that the manganese in the iron was only 0.50 pct, which illustrates how high slag basicity, temperature, and silicon content can over-balance the countereffect of a low manganese level.

In Fig. 9 of this same paper<sup>4</sup> is shown the distribution curve of the sulphur distribution ratio for the individual casts which varies from 70 to 160. These upper values of 150 and 160 represent about the maximum values that we have obtained on individual casts. The usual range of observed values of this ratio vary from 20 to 125 based on composites of 12 and 24 hr samples (2 to 4 casts).

### External Desulphurization of Iron

It has been suggested that the problem of sulphur in iron can best be solved by operating the blast furnace without reference to the sulphur, which is then brought down to a satisfactory level by some special treatment of the liquid iron after it has been removed from the furnace.

External desulphurization has been accomplished mainly with alkalis. This method has been employed in many foundries for some time as well as a number of blast furnace plants for the treatment of off-casts high in sulphur. As a result, a number of papers have been written on this subject.

Various methods for external desulphurization may be listed and discussed briefly as follows:

The use of alkalis or mixtures as follows: soda ash ( $\text{Na}_2\text{CO}_3$ ) with 58 pct  $\text{Na}_2\text{O}$ ; caustic soda ( $\text{NaOH}$ ) with 76 pct  $\text{Na}_2\text{O}$ ; soda ash and caustic soda mixtures; and soda ash, limestone, and fluorspar mixtures. The alkalis are produced in granular or briquette form. The advantage of the latter is that boiling action is prolonged by slower melting of the lumps. These alkalis are commonly added to the bottom of the ladle before casting or to the iron stream flowing into the ladle. Sometimes a combina-

tion of both methods is used. Obviously contact between alkali and metal is obtained by the stirring action of the falling iron stream and the boiling action of the desulphurizing material. Such a means of making contact is bound to be erratic from one addition to another. Hence a variable amount of sulphur reduction results from cast to cast. It has also been found that a high sulphur content in the iron can be lowered quite consistently to the 0.040 to 0.050 pct range, but considerable difficulty is encountered in attempting to bring it down near 0.030 pct or below. Further complications arise from the reaction of this alkaline slag with the silica refractory of ladles and mixer. This in turn results in increased refractory costs. Finally, if proper separation of this desulphurizing slag and kish is not made at the ladles or mixer, it will be charged into the open hearth furnaces. How much of this extra sulphur is oxidized and removed in the gas phase, or passes out with flush slag in heats using a runoff practice, is quite debatable. An elaborate layout of ladles equipped with facilities for the separation of the spent desulphurizing slag is discussed by Evans.<sup>5</sup> This method eliminates some of the variation in sulphur reduction but it will not aid in the desulphurization to a low sulphur level.

The desulphurization of iron has also been accomplished with calcium carbide. Laboratory experiments on the method of adding this material were made by Wood<sup>6</sup> and coworkers. It is interesting to note that by rapid stirring in of fine calcium carbide below the iron surface a sulphur elimination ranging from 63 to 93 pct was obtained. This illustrates the intimate contact that must be made between surfaces of liquid metal and the desulphurizing media.

It has been reported by Warren<sup>7</sup> that the sulphur content of iron decreased somewhat during an abnormally long interval between casting into transfer ladles and delivery to the mixer in the open hearth shop. A detailed study of metal and kish samples from Warren's practice, which also included X-ray diffraction patterns, indicated the presence of  $\text{MnS}$ . These data tend to confirm the reality of  $\text{MnS}$  separation from iron. However, this should occur only when manganese and sulphur contents are high enough, and the final temperature low enough, to cause supersaturation. For illustration, Fig. 1 presents a family of solubility curves of manganese and sulphur in liquid iron for various temperatures based on Joseph and Holbrook's findings.<sup>8</sup> If the analyses of the above mentioned samples are compared to this chart the effects indicated are as follows:

When cast into the ladle at the blast furnace the iron contained 0.085 pct S and 1.90 pct Mn. The iron cooled during the 3 to 4 hr travel to the mixer and when it reached a temperature of approximately 2490°F solid  $\text{MnS}$  began to separate. This continued until the final composition at the mixer was 0.042 pct S and 1.82 pct Mn. On this diagram this corresponds to approximately 2380°F. On the basis of the solubility diagram, it would usually be possible to reduce the sulphur on high sulphur casts by cooling the ladles of metal to approximately 2400°F. The final sulphur content, at this temperature, would obviously depend on the manganese content of the iron. For example, if the manganese content were below 1.0 pct the final sulphur content would not be reduced below 0.090 pct. However, if the manganese content were 1.75 pct, the final sulphur would then be down to 0.05 pct; and if the manganese content

were further increased to 2.8 pct, the sulphur would be reduced to 0.03 pct.

Prerequisites for this method of sulphur reduction are high manganese iron, longer delivery time to the mixer, and lower temperature iron entering the mixer. The two latter requirements are the most objectionable from the standpoint of speed of operation. Besides these three requirements a good separation of the solid MnS and kish should be made before the iron enters the mixer.

In general, it appears evident at this time that future developments in desulphurization between blast furnace and open hearth should trend toward improved and better controlled contact between metal and desulphurizing agent; minimum costs of material and labor; and less cooling of the metal. Increased dependence on lime, as the cheapest and most effective sulphur absorber, seems probable. If the desulphurizing unit could be incorporated in, or take the place of, the regular iron mixer, this would be best adapted to the flowsheet of the normal steel plant.

### Sulphur Problem of the Open Hearth

The reduction of sulphur in the open hearth bath is more difficult and is limited to much smaller amounts than the reduction in the blast furnace. This is exemplified by: 1—the difference in sulphur distribution ratios, with observed values of from about 2 to 12 in the open hearth, whereas in the blast furnace the range is from 15 to 150; 2—the inherent nature of the open hearth, with its pattern of heat flow largely from above through the slag layer, limits the practical slag weight to from 8 to 18 pct of the metal weight as compared to a range of 40 to 150 pct in various blast furnace practices.

Consequently the sulphur burden or total sulphur input into the individual open hearth heats becomes of primary importance. Before discussing various specific sulphur balances and burdens, it might be well to consider briefly the different items that make up the input side of the sulphur balances. These items are listed as follows:

**Liquid Iron or Hot Metal:** The amount of sulphur introduced into the open hearth charge in the liquid iron usually accounts for 27 to 50 pct of the total sulphur input. This of course depends mainly on the amount of liquid iron addition which usually corresponds to from 40 to 70 pct of the total weight of scrap and hot metal. Open hearth shops making much of their product to rather low sulphur specification may desire the percentage of sulphur in the hot metal to average below 0.030 pct. Shops producing steel with a less critical sulphur specification frequently average 0.040 pct S or higher in the liquid iron.

There is another source of sulphur which is introduced with the hot metal and is commonly called kish. This material is heterogeneous and erratic in both physical and chemical makeup. It consists of oxidized metal shot, coke fines (thrown on the top of the iron ladles), fire clay, silica (from ganister refractories and sand of the runner and cast house floor), separating particles of MnS, and frequently blast furnace slag. The primary components of the kish which contribute sulphur are the coke fines, the slag, and the MnS phase, and they represent a wide range of sulphur contents (see Table IV). The rather high silica content (10 to 35 pct) of kish has a deleterious effect on the sulphur removal from the open hearth bath because it counteracts the basicity of the slag. These detrimental effects of kish are obvi-

Table IV. Typical Ranges of Sulphur in Some Charge Materials

| Materials              | S. Pct    |
|------------------------|-----------|
| Limestone              | 0.03-0.20 |
| Burnt lime             | 0.02-0.25 |
| Raw dolomite           | 0.02-0.40 |
| Single burned dolomite | 0.02-0.25 |
| Double burned dolomite | 0.01-0.20 |
| Fluorspar              | 0.10-2.00 |
| Kish                   | 0.30-0.80 |

ously most serious in the case of open hearth heats without runoff slags. The kish probably tends to float on the slag in the open hearth as the iron is charged. Some rather recent samplings of runoff slags have indicated that the first portions of the runoff are often higher in sulphur than would be expected from slag-metal equilibria. These data suggest that much of the kish entering the open hearth is floated or carried out by the runoff slag, at least in those heats having the start of flush immediately or shortly after the time of the hot metal addition.

**Scrap:** The amount of sulphur introduced into the open hearth charge from scrap is somewhat variable, obviously depending on its sulphur content and the amount charged (governed largely by the hot metal percentage of the particular shop). The sulphur content of the scrap that is produced in a given shop should be known reasonably well, especially if steps are taken to separate the high sulphur steel scrap from the ordinary scrap lower in sulphur. However, the sulphur content of purchased scrap is practically unknown; this is especially true of the miscellaneous scrap. This introduces considerable uncertainty in the sulphur burden if large quantities of purchased scrap are charged.

Recent findings of Osborne<sup>9</sup> indicate that the rust attached to the scrap may have a sulphur content 15 to 18 times greater than the base metal. From Table I of his paper, the average sulphur content of the base metal was 0.0206 pct and that of the rust accompanying this scrap was 0.324 pct. In this connection, we have collected different rust samples from various scrap piles of our plants. These rust samples had been formed over a period of one to seven years and gave sulphur contents varying from 0.20 to 1.10 pct with an average of 0.50 pct. It is interesting to note that if we assume that the scrap averaged 95 pct metal with 0.030 pct S and 5 pct rust with 0.50 pct S, the aggregate sulphur content of the scrap would then be 0.054 pct. This would result in a very appreciable increase in sulphur burden if an appreciable amount of rust were charged on some heats. However, it is difficult to know what percentage rust is present in most scrap and there is also the possibility that the sulphur in the rust would be vaporized out during melting, although Fig. 2 of Osborne's<sup>9</sup> paper does not tend to substantiate this idea.

From this discussion it can be seen how difficult it is to obtain a representative sulphur content for the scrap to be used in calculating a sulphur input balance. To obtain such a value good clean scrap free of rust and of known composition must be used.

**Limestone, Burnt Lime, and other Fluxes:** The chemical analyses of numerous shipments of the various fluxes (see Table IV) have revealed a wide variation in sulphur content. This variation usually represents differences between quarries, although considerable variation sometimes exists in shipments

Table V. Comparison of the Ladle Sulphur Content of Heats Charged with High and Low Sulphur Limestone Content

| Time              | No. of Heats | Avg. S Content of Limestone | Avg. Pct Ladle S |
|-------------------|--------------|-----------------------------|------------------|
| First six months  | 616          | 0.160                       | 0.0285           |
| Second six months | 872          | 0.045                       | 0.0245           |
| Difference        |              | 0.115                       | 0.0040           |

from the same quarry. Table IV gives typical ranges from a large number of individual determinations.

The users of fluxes high in sulphur content are very likely to pay a penalty in the form of higher final sulphur contents. This is illustrated by the following example which is a comparison of heats for similar low carbon grades made over two consecutive six-month periods. The open hearth fuel was natural gas (hence there was no sulphur pickup from the furnace gases). The steel was made on a runoff practice with comparable limestone charge, scrap, and iron analysis. The main difference was the sulphur content of the limestone as shown in Table V.

This is quite understandable when it is realized that the ratio of weight of steel to the weight of tap slag varies from about 7:12, whereas the slag to metal sulphur ratio at tap is most commonly about 4:7. Even on heats with maximum sulphur specifications of 0.04 to 0.05 pct, limestone with more than around 0.25 pct S may add more sulphur to the burden than it can remove; in heats for steel with maximum sulphur of 0.020 pct or below, this critical value may be down toward 0.10 pct S or lower. For the same reason the sulphur content of burnt lime and dolomite should be kept as low as possible.

It is worth remembering that the moderate amount of sulphur removed in runoff slag may come from charge ore, scrap, hot metal, or dolomite on banks, but all the sulphur in the charged limestone contributes to the sulphur carried in the final slag and metal at tap. Higher sulphur in dolomites used may contribute sulphur to both runoff and tap slags.

*Ore, Sinter, and Miscellaneous Additions:* The sulphur content of ore, sinter, and alloy additions should be kept as low as possible. It is realized that often only one type of ore, sinter, or other material is available at the particular plant and must be used. However, when a choice can be made between similar materials that are reasonably comparable in other respects except sulphur contents, then the one which has the lowest sulphur content should be used.

*Fuel:* The total amount of sulphur charged from all the sources just discussed above, from hot metal to ore, usually varies from a low of 0.65 lb to a high of 1.25 lb S per ton of steel.

In considering open hearth fuels it is found that the total amount of sulphur available from this source varies widely with the different types of fuels. Also that all the fuels except natural gas have an amount of sulphur that exceeds the total from all other input sources. This is illustrated in Table VI which represents typical values for present day fuels.

It is very fortunate that this relatively high sulphur potential of the fuel is transferred to the slag-metal system at a very low efficiency. With fuels having lower sulphur contents (similar to fuels used 12 to 17 years ago), it is doubtful whether any appreciable amount of sulphur enters the metal.

This point will be discussed in more detail a little later. The studies of Diehl<sup>10</sup> and others of the sulphur equilibrium between metal and sulphur-containing gases show that an increase in oxygen pressure decreases the tendency toward sulphur absorption from the gas. During the melting of scrap in the open hearth the scrap is piled fairly high in the furnace and is bathed by portions of the flame containing incompletely combusted fuels to give a low oxygen pressure, favoring sulphur pickup from the fuel.

Conversely the factors which minimize the sulphur pickup from a high sulphur fuel during scrap melting may be enumerated as follows: 1—rapid scrap charging, 2—maintenance of a high ratio of air to fuel with a short oxidizing flame, 3—rapid melt down, and 4—avoidance, as much as possible, of a high pile of scrap that remains for a considerable period of time in the direct path of the flame.

It has frequently been found, when calculating sulphur balances, that the input side was less than the output. This difference has often been captioned "unaccounted for (from furnace gases)." It is thus assumed that the unaccounted for sulphur represents the sulphur absorbed from the fuel during the scrap melting. Actually, however, the amount of unaccounted for sulphur which can be attributed to the fuel is rather difficult to estimate. For example, under our discussion of the sulphur content of scrap it was pointed out that 5 pct rust on the scrap would increase the aggregate sulphur content approximately 80 pct. Sulphur contents in such rust, in kish spilled in with hot metal, and in eroded dolomite are frequently overlooked. The point is that an error in the sulphur content of some of the charged materials could easily account for all or nearly all the missing sulphur of the balance in most cases. The fact that, when the sulphur content of the fuel is relatively low, or only moderately high, the amount of sulphur absorbed during scrap melting is rather small tends to be substantiated by data obtained approximately 15 years ago when the sulphur content of fuels was lower than that in present fuels.

These data from several plant practices are tabulated in Table VII and, for each plant, represent an average of ten heats of the same grade of steel. All 50 heats were carefully made with complete details of weights and analyses of incoming materials and outgoing products. It is believed they represent a very good set of data for calculating balances. Table VII is confined to the sulphur balance data.

As nearly as could be ascertained, all the heats were charged with fairly clean scrap and the amount of rust introduced with the scrap was rather insignificant, consequently the sulphur content of the base scrap metal was probably close to the true value. Hence it would seem that the amounts of sulphur charged into these heats are truly representative. Thus for these particular heats the unaccounted

Table VI. Average Amount of Sulphur Available in the Various Fuels

| Materials                 | Lb S per Ton Steel | Equivalent Pct S in Steel |
|---------------------------|--------------------|---------------------------|
| All other input materials | 0.65 to 1.25       | 0.033-0.063               |
| Natural gas               | 0                  | 0                         |
| Tar and natural gas       | 1.25               | 0.063                     |
| Oil                       | 2.15               | 0.108                     |
| Tar                       | 2.50               | 0.125                     |
| Tar and coke oven gas     | 4.25               | 0.213                     |
| Coke oven gas             | 6.00               | 0.300                     |

for sulphur probably represents a fairly good estimate of the sulphur pickup from, or loss to, a group of fuels with low to moderate content of sulphur.

In discussing the results of Table VII, consider first the data from plants A and B:

In the case of plant A, the fuel was a mixture of 62 pct natural and 38 pct coke oven gas with a relatively low total sulphur content of 0.79 lb per ton (from the coke oven gas). The unaccounted for sulphur amounted to only 0.01 lb per ton or 1.5 pct of the total sulphur charged and is on the output side of the balance, indicating a loss of sulphur from the slag-metal system to the gas phase.

In the case of plant B, a mixed fuel was used which consisted of 58 pct natural gas and 42 pct tar. Again this fuel had a relatively low total sulphur content of 0.70 lb per ton (from the tar). The unaccounted for sulphur of the balance amounted to 0.11 lb per ton or 12.9 pct of the total sulphur, once more on the output side of the balance. The unaccounted for sulphur of the balance (0.11 lb per ton) seems rather high and could be due, in part, to some other errors of the sulphur contents of input or output materials. In any case, the data of this plant indicate a net loss of sulphur to the gas phase.

In discussing the remaining data of Table VII the result of plants C, D and E will be considered together as follows:

Two plants (C and D) used producer gas whereas the third plant (E) used 80 pct tar and 20 pct coke oven gas. The sulphur content of these fuels varied from 1.80 to 2.17 lb S per ton steel, or more than double the sulphur content of fuels of plants A and B. The unaccounted for sulphur, of the balance, varied from 0.01 to 0.03 lb S per ton steel or 1.5 to 4.4 pct of the total sulphur of the balance. In all three cases the unaccounted for sulphur is on the input side of the balance indicating a pickup of sulphur from the fuel. If we consider the fuel as contributing all the unaccounted for sulphur, it will be noted that this is fairly small and amounts to only 1.5 to 4.4 pct of the total sulphur burden. If this unaccounted for sulphur is compared with the sulphur content of the fuel, the low efficiency of the sulphur transfer is apparent:

Plant C

$$\frac{0.03 \text{ lb S per ton unaccounted for}}{1.84 \text{ lb S per ton in fuel}} \times 100 = 1.6 \text{ pct}$$

Plant D

$$\frac{0.03 \text{ lb S per ton unaccounted for}}{2.17 \text{ lb S per ton in fuel}} \times 100 = 1.4 \text{ pct}$$

In other words it appears that a maximum of 1.0 to 2.0 pct of the sulphur of the fuel is absorbed by the slag-metal system during melting at these intermediate levels of fuel sulphur content.

In some of the present day higher sulphur fuels (4.0 to 6.0 lb S per ton steel) which some of the plants are forced to use from time to time, a larger transfer and absorption of sulphur from the fuel is noted. To illustrate this point the experience of several plants may be noted briefly as follows:

One plant normally had a supply of open hearth fuel oil that averaged 1.0 pct S. With this fuel the desired ladle sulphurs were obtained with an average slag basicity of approximately 2.6. For a period of one to two months this plant had to use a fuel oil containing over 3.0 pct S. It was soon found that

in order to finish the heats with the same ladle sulphur as before, the slag basicity had to be increased to 3.5 to 3.8. After the plant again returned to its regular oil supply containing 1.0 pct S the lime and limestone consumption decreased to its regular value. Several sulphur balances were made on another plant using coke oven gas with high sulphur contents (4.0 to 5.0 lb S per ton steel). These particular sulphur balances are fairly accurate but probably not as good as those shown in Table VII. Consequently, we cannot be sure that all the unaccounted for sulphur came from the fuel, though it is quite possible that a large fraction was contributed by the fuel. This will be discussed further a little later in connection with some other data. Returning to the sulphur balances, the unaccounted for sulphur varied from 0.17 to 0.34 lb S per ton steel. Comparing these values with the sulphur content of the fuel the following variation is noted:

For one balance:

$$\frac{0.17 \text{ lb S per ton unaccounted for}}{4.0 \text{ lb S per ton in fuel}} \times 100 = 4.3 \text{ pct}$$

For another balance:

$$\frac{0.34 \text{ lb S per ton unaccounted for}}{4.8 \text{ lb S per ton in fuel}} \times 100 = 7.1 \text{ pct}$$

Thus it appears from these data that a maximum of 4.0 to 7.0 pct of the sulphur in the fuel was transferred to, or absorbed by, the slag-metal system during melting, at these high levels of sulphur content of the fuel. This gain of sulphur from the fuel is of sufficient magnitude to raise the ladle sulphur content by approximately 0.006 to 0.010 pct S. Other experiments with high sulphur coke oven gas have shown that a substantial reduction in final ladle sulphur contents can be obtained if desulphurized coke oven gas is used during the scrap melting period of the heat. One or more erratic conditions probably exist in normal practice, causing variability in sulphur absorption from gases; further study is needed here.

The sulphur problem of the open hearth, as discussed so far in this paper, has been centered on the input of the sulphur balance including the various types of fuel. The remainder of this discussion will

deal with the output side of the sulphur balance and with the metallurgical problems that arise when it is desired to lower the sulphur content of the bath during the refining period. The situation can best be outlined by tabulating a couple of sulphur balances and referring to certain points of interest. For this purpose the complete sulphur balances of plants D and E of Table VII are repeated more in detail in Table VIII.

It will be noted that a difference exists between the total input sulphur of the two plants. Plant D has a heavier sulphur burden input, largely due to the higher sulphur content of the fluorspar and limestone. The larger sulphur input of plant D required a larger slag volume and heavier limestone charge to give the higher sulphur ratio of 9.3 as compared to 5.1 for plant E. The most interesting point in the practice at plant D is that the high slag basicity of 3.94 produced a sulphur content of only 0.024 pct, whereas plant E obtained 0.023 pct S in the metal with a slag basicity of only 2.32. Obviously such a practice as that used by plant D is uneconomical both in cost of material and increased time of heat. At a later period, plant D obtained new sources of these materials with lower sulphur contents and was able to decrease slag volume and basicity without changing the sulphur content of the final steel.

It is generally agreed by most investigators that the open hearth process is a poor desulphurizer, so that a small amount of excess sulphur requires a relatively large excess of basic materials (CaO and MnO) and large slag volumes. It is further agreed that the observed sulphur ratio (of sulphur in slag to sulphur in metal) is increased by free CaO (that CaO remaining after the SiO<sub>2</sub> and the P<sub>2</sub>O<sub>5</sub> have been chemically satisfied) and free MnO in the open hearth slag.

There is some disagreement among various investigators on the method of calculating the sulphur ratio between slag and metal from the ordinary open hearth slag analysis. One method of calculation has been proposed by Darken and Larsen<sup>11</sup> and another by Grant and Chipman.<sup>12</sup> Somewhat different results from the two methods illustrate the difficulties that arise with a multicomponent system such as an open hearth slag.

The sulphur balances of Table VIII were for heats of a no-runoff practice, with a relatively low percentage of liquid iron in the charge, in the range of 35 to 45 pct. In recent years it has been the practice for a number of plants to operate with much higher liquid iron percentages in the range of 50 to 70 pct. Such a practice necessitates running or flushing off the early premelt slag prior to the lime boil. Obviously such a practice has both advantages and disadvantages. However, these will be discussed only with respect to the sulphur problem.

The advantages are that if the runoff practice is properly executed to give a maximum runoff slag, approximately 55 to 65 pct of the total silica and 14 to 20 pct of the total sulphur is eliminated.

The disadvantages are as follows: In a good runoff slag practice approximately 55 to 65 pct of the total Mn is eliminated as MnO. As a result, the refining slag is lower in MnO which in turn produces a lower sulphur ratio between slag and metal. A further disadvantage occurs when a poor slag runoff is obtained. In such cases only about 30 to 50 pct of the total silica and 8.0 to 13.0 pct of the total sulphur is removed from the system. The extra silica, and also the sulphur that is not flushed off, are added to the refining slag. This additional silica requires practically all the extra charged limestone to neutralize it. Consequently the slag after melting is not very basic and requires variable, and frequently large, additions of extra burned lime to produce the desired desulphurization of the bath. Such a condition causes poor control of slag shaping and lowered production rate.

The importance of maintaining a good runoff of slag from heat to heat cannot be overemphasized. This requires constant supervision from the foreman and furnace operator.

### Sulphur Problems After Tap

Ordinarily there is no appreciable change in sulphur content of steel as it is tapped from the furnace and teemed into the ingot mold. Occasionally heats are encountered in which the final steel sulphur has increased 0.002 to 0.004 pct. It will be found that in such cases the tap slag is of low basicity ratio, nearly on the acid side. In addition such heats are usually blocked and silicon killed. Consequently the furnace slag, already low in basicity as it enters the ladle, becomes more acid because of the extra silica from the ferro-silicon ladle addition and because of the ladle refractory erosion, the resultant effect being to cause a reversion of both sulphur and phosphorus to the metal.

In contrast we have found that silicon-killed steel to which calcium-silicon ladle additions have been made show a decrease in final sulphur. We have carefully checked nearly a dozen heats to which 3.5 to 5.0 lb CaSi per ton of steel was added and find that sulphur content of the steel has decreased 0.002 to 0.004 pct from the tapping to the teeming operation.

### Summary

In the steelmaking cycle the largest source of sulphur is in the coal used to make coke for the blast furnace. Efforts to remove any appreciable amount of sulphur from the coal or the coke have so far been impracticable because of the low activity of the organic sulphur in the coal and coke and because of the price limitations involved in treating a low cost material such as coke.

Sulphur balances of the blast furnace indicate that 88 to 94 pct of the sulphur input is from the coke and 94 to 96 pct of the total sulphur is carried out in the blast furnace slag.

Cokes with average sulphur content in the range 0.80 to 1.80 pct have been charged in the blast furnace and iron with sulphur content of 0.036 to 0.042 pct has been produced. This was possible with an increase in slag basicity, addition of dolomite to produce a slag with 5 to 8 pct MgO, and by increasing the manganese content of the iron with increased open hearth slag additions.

External desulphurization of the iron has been accomplished by the use of alkalies and calcium carbide. Also iron with high manganese content can be desulphurized by holding the ladles for an extra 2 to 4 hr and thereby lowering the iron temperature to allow the separation of MnS.

The reduction of sulphur in the open hearth is more difficult than in the blast furnace. This is illustrated by the sulphur distribution ratios which are 10 to 12 times lower in the former process. For this reason the sulphur content of each raw material charged should be kept to the absolute minimum. This is especially true of limestone, burnt lime, the various dolomites, fluorspar, kish, and also rusty scrap. Evidence is presented to show that the charging of fluxes high in sulphur results in several points increase in the final ladle sulphur analysis.

The total amount of sulphur available from the open hearth fuels varies widely with the different types of fuels. All the fuels except natural gas carry in an amount of sulphur that exceeds the total from all other input sources. Although the percentage of this sulphur which is transferred to the slag metal system is generally rather poor, it tends to increase at the higher fuel sulphur levels, so that those fuels highest in sulphur content do contribute an appreciable amount. The amount of this sulphur absorption is variable with furnace operating conditions during scrap charging and melting.

Complete sulphur balances of open hearth heats are shown; these indicate the importance of minimum weight of  $\text{SiO}_2 + \text{P}_2\text{O}_5$  in the tap slag, also the need to both increase basicity and increase manganese oxide of the slag to further lower the sulphur content of the bath during the refining period.

## Technical Note

## Useful Etchants for Electron Metallography

by William L. Grube

**S**PECIMEN preparation for electron metallography involves several steps, such as polishing, etching, replicating, mounting, and shadowing. Although each step must be done with care, the operation requiring the utmost attention is etching.

Proper etching is important because the relief pattern developed on the surface of the specimen by the etchant, and reproduced as minute differences in thickness of the replica, determines entirely the amount of detail seen in the final micrograph. The characteristic colored stains, sometimes used in light metallography to simplify identification of certain microconstituents, cannot be tolerated because there

is danger of introducing artifacts in the replicating operation. It is also quite difficult to remove plastic replicas from stained specimens. A suitable etchant for electron metallography must, therefore, in all cases exhibit a preferential attack upon each of the microconstituents present sufficient to result in a difference in surface elevation.

When only two microconstituents are present, it is not too difficult to find a suitable etchant since their physical or chemical properties are generally sufficiently different to result in a marked difference in attack by the etchant. For example, picral (a saturated solution of picric acid in methanol used as an immersion etch) is a satisfactory etchant for the specimen shown in Fig. 1 consisting of iron carbide particles embedded in a ferrite matrix.<sup>1</sup>

Picral is less satisfactory when used to etch fine lamellar pearlite shown in Fig. 2. Although the relief is sufficiently developed, the etchant has left a residue upon the surface as indicated by the presence of small opaque particles. Moreover, some irregularities appearing in the carbide lamellae indicate that the replica adhered to the specimen tightly and suffered some disturbance upon removal.

A more satisfactory etchant for fine pearlite is ferric chloride-hydrochloric acid (1 pct HCl; 2 pct  $\text{FeCl}_3$  in methanol). As shown in Fig. 3, this etchant leaves a cleaner surface for replicating. Also differences in orientation of the pearlite colonies are more clearly resolved.<sup>1</sup>

As pointed out earlier by Ellis<sup>2</sup> it is quite difficult to etch the harder microstructures of steel (those containing martensite as-quenched, slightly tempered, or both) satisfactorily for electron metallography. For as-quenched steels, the etchant must, essentially, differentiate between martensite and retained austenite. This picral will not do, as indicated in Fig. 4. A modified nital etchant<sup>3</sup> consisting of 2 pct nital containing 0.5 to 1.0 pct zephiran chloride is almost ideal for this structure as shown in Fig. 5. Etchants which develop the retained austenite to this extent yield micrographs suitable for making quantitative measurements. Allten's reagent<sup>4</sup> is also very satisfactory for developing retained austenite as shown by Fig. 6. For simple structures, there is no particular advantage in using Allten's reagent. For more complicated structures containing smaller amounts of retained austenite it shows promise of being more satisfactory because, being used electrolytically, it can be controlled more effectively. It should be pointed out, however, that electrolytic etches may prove unsatisfactory for electron metallography because it has been found that a residue is sometimes left at phase boundaries. This residue is difficult to remove and often covers up much detail.

In structures containing more than two microconstituents it often becomes imperative to use a modified etchant. For example, Fig. 7 shows the microstructure of a specimen of S.A.E. 52100 steel etched in 2 pct nital. The undissolved carbide and tempered martensite are well developed, but there is no differentiation between the untempered martensite and retained austenite. When this structure is etched with 2 pct nital containing zephiran chloride, the complete structure as shown in Fig. 8 is developed.

In cases where it is not possible to develop the microstructure completely with a single etchant, a

composite etch (two etchants in succession) may be used. Such is the case with cemented carbide compositions containing both tungsten and tantalum carbide. An electrolytic alkaliferri cyanide etch (equal parts 10 pct potassium hydroxide and 10 pct potassium ferricyanide at 4 volts) develops only the angular shaped tungsten carbide grains. If an additional 3 pct nital is used after the above etch, the complete structure as shown in Fig. 9, is developed. The nital etch effectively reveals the smooth, round-contoured grains of tantalum carbide by attacking the cobalt binder.

When a satisfactory composite etch cannot be found, the only recourse is to use two or more etches independently. Such a procedure is not entirely satisfactory, but it is sometimes the only way to study the complete microstructure. For example, an electrolytic, 5 pct hydrochloric acid etch is effective in developing the secondary carbide precipitate in high temperature alloys. The primary carbide "aggregates," however, are either unattacked or etched so deeply that a faithful replica cannot be obtained, thereby precluding the possibility of interpreting the microstructure. On the other hand, a vacuum-cathodic etch<sup>5</sup> develops the structure of the primary carbide well as shown in Fig. 10. The secondary carbide particles which surround the primary carbide phase, however, are only faintly visible. Neither etchant is completely satisfactory, but the use of both permits a more accurate interpretation of the structure. In summary, results of the use of various etchants on typical metallographic specimens have been shown. From the results, it is evident that the success of a particular etchant in electron metallography cannot always be predicted from previous experience in light metallography. However, the etchants found to be satisfactory in light metallography should serve as starting points for the development of etchants more suitable for electron metallography.

# Solubility of Gaseous Nitrogen in Gamma Iron and the Effect Of Alloying Constituents — Aluminum Nitride Precipitation

by L. S. Darken, R. P. Smith, and E. W. Filer

The solubility of nitrogen gas in purified iron and low alloy steels is determined for the  $\gamma$  region (930° to 1350°C). The diffusivity of nitrogen is estimated from the rate of approach to equilibrium. The investigation of aluminum-killed steels, held in nitrogen, discloses precipitation of aluminum nitride, the solubility of which is determined.

ALTHOUGH several investigations of the solubility of nitrogen gas in  $\gamma$  iron have been reported, all have made use of the method adopted by Sieverts in his classic work, whereby the solubility is determined by the pressure or volume change of the gas. The agreement between different investigators\* is rather poor, particularly as compared to the self-consistency of results of several individual investigators. The present report represents a portion of our investigation of the equilibrium of nitrogen and nitrogenous atmospheres with iron and steels. The method adopted in this temperature region (910° to 1400°C) consists of holding the specimen in gaseous nitrogen, quenching (or cooling), and determining the nitrogen content by direct analysis (solution in acid followed by distillation and titration of the ammonia).\*\*

Up to 1050°C a 20 in. vertical wire-wound (Kanthal) furnace was used; this was wound in three sections so that by proper adjustment of relative currents, and use of a modulator<sup>1</sup> and a commercial controller (using a chromel-alumel control couple), a zone almost 6 in. long could be maintained uniform within a few tenths of a degree. Since the temperature coefficient of the nitrogen solubility is low, the full precision was not utilized and a variation of 1° to 2° was tolerated; a variation of a similar amount also occurred occasionally between the beginning and end of the experiment. At higher temperature a vertically mounted, tubular Globar furnace and control unit was used; the zone of uniformity (1° to 2°C) was here limited to about 2 in.; fluctuations with time were comparable to those in the wire-wound furnace. Reported temperatures were measured by use of a platinum-platinum-rhodium thermocouple, which was frequently com-

Fig. 1.—Nitrogen absorption as a function of time for electrolytic iron suspended in nitrogen gas (+1 pct  $H_2$ ). The dashed curve and that for 1348°C have the theoretical form for a diffusion controlled process with constant surface concentration.

pared with a similar standard couple which was calibrated at the gold and palladium points and also compared with one certified by the Bureau of Standards; error from this source is believed to be less than 1°C.

Nitrogen gas from a commercial cylinder was mixed with slightly over 1 pct H by use of a gas mixer described previously.<sup>2</sup> This mixture was passed over hot copper and through ascarite and phosphorus pentoxide to remove oxygen and water vapor. The purified gas contained 1.05 pct H. This procedure was adopted to prevent the formation on the specimens of oxide film, which is well known to be nearly impervious to nitrogen; its success was attested by

\* One of the difficulties of this method lies in the determination of the so-called "hot volume"—that is the amount of nitrogen (or other substance) in the gaseous phase. This subject was investigated and discussed by M. H. Armbruster, *Journal Amer. Chem. Soc.* (1943), 65, p. 1043.

\*\* The authors are greatly indebted to Glenn W. Momeyer for the analytical work of this investigation.

\* Irons 1 and 2 are carbonyl and electrolytic respectively. Spectrographic analysis indicated the presence of no other metallic elements in excess of 0.001 pct except for 0.02 pct Ni in each and 0.05 pct Cu in the electrolytic iron.

† Metallic aluminum; this is believed negligibly small in the steels which were not aluminum-killed and for which no value is tabulated.

the fact that specimens pulled up and cooled in the glass head of the furnace exhibited no tarnish except in the case of the high silicon steels. In this latter case a "getter" of transformer steel was ultimately suspended beneath the specimens. The purified gas was led through glass tubing (with two butt joints of treated rubber) and introduced into the porcelain furnace tube (¾ or 1 in. ID) through a mercury seal at the bottom. At the top was a ground pyrex joint, the male portion of which was sealed to the porcelain. The gas was discharged to the atmosphere through a long glass tube to prevent any breathing of air into the furnace. Although barometric readings were taken, these are not reported since the effect of departures from 760 mm was negligibly small. Similarly the effect of the 1 pct H on the nitrogen solubility is negligible; by Sievert's law

this lowers the nitrogen solubility by only ½ pct—for example by 0.0001 pct out of 0.02 pct.

The composition of the irons and steels used is given in Table I. Except as noted below these were in sheet form; specimens were cut about ½ in. wide and 4 or 2 in. long, depending on the uniform zone of the furnace used. They were pickled and sanded. Several specimens were frequently run simultaneously; small porcelain rings were used as spacers in this case. The suspension wire was of iron. The series of aluminum steels were initially in bar form (¾ in. diam); half disks were used as specimens. The ingot iron used in an attempt to determine the diffusivity was a cylinder 4 in. long and ⅝ in. diam.

### Solubility of Nitrogen in $\gamma$ Iron

It was originally thought that the slow step in achieving equilibrium between specimen and atmosphere would be the diffusion of nitrogen through the specimen. It was hoped that both the solubility and the diffusivity could be determined by a time series. Electrolytic iron was used for this purpose and the results are shown in Fig. 1. Also shown in this figure is the form<sup>3, 4</sup> of the theoretical curve that would be expected if the surface of the specimen were saturated rapidly and remained so. The square root of time is used as abscissa in this figure to facilitate comparison with the theoretical curve (dashed) which is linear and of finite slope in the vicinity of

Fig. 2—The solubility of nitrogen gas (at atmospheric pressure) in  $\gamma$  iron.

the origin, becoming concave downward as saturation is approached, and eventually leveling off. At the lower temperatures the experimental data do not even approximate this form; the boundary condition is undoubtedly not satisfied and the diffusivity cannot reliably be computed from these data. It would seem that surface adsorption rather than diffusion is the slow step in attaining equilibrium. Even at 1200°C the same conclusions would seem to apply though to a lesser extent. This may be seen by comparison of the experimental data with the theoretical curve for diffusion into a slab under the condition of constant surface concentration. For the data at 1348°C, the curve in Fig. 1 is drawn with the theoretical form and corresponds to the diffusivity:

$$D = 3.1 \times 10^{-6} \text{ sq cm sec}^{-1}$$

These time series at least indicate the minimum time required for approximate equilibration. In each case, except for the lowest temperature, two specimens were run for a substantially longer time. At the lowest temperature a much thinner specimen was used to achieve equilibrium. The solubility of nitrogen gas in iron, as thus determined, is given in

Fig. 3—Penetration curve for nitrogen in iron rod.

Table II. The solubility in several low alloy steels is also included. As indicated here and substantiated later, the extraneous constituents have a negligibly small effect; hence all these results at or near a given temperature are averaged. These averages, as well as the individual results for iron, are plotted in Fig. 2 and compared with the results of other investigators.<sup>5-8</sup> The results are represented remarkably well by a straight line, whose equation is:

$$[\text{Pct N}] = 0.0404 - 1.2 \times 10^{-5} T$$

#### Approximate Diffusivity at 955°C

In order to verify the previous conclusion that the slowness in the lower temperature region is due to failure to establish surface saturation and to determine the diffusivity, another series of experiments was run. An ingot iron cylinder (4 in. long, 5/8 in. diam) was suspended in the furnace in the same manner as before. After a predetermined time (23 1/2, 94, or 209 hr) the cylinder was quenched and subsequently turnings were taken on a lathe, after discarding the ends. The nitrogen content of the layers is shown in Fig. 3. It is quite apparent that the surface layer did not become saturated even in 209 hr. The diffusivity of nitrogen may be determined directly from its definition. By graphical integration the mean nitrogen content was computed for each time. The rate of entrance of nitrogen per unit area, as determined therefrom, divided by the concentration gradient (at the surface) at the corresponding time gives a mean:

| 1342            | (From Fig. 2) |          | 0      | 0.021              |
|                 | 12            | 16       | 0.20   | 0.020              |
|                 | 13            | 16       | 0.58   | 0.018              |

$$D = 1.9 \times 10^{-7} \text{ sq cm sec}^{-1}$$

The same result was obtained using a more complicated method. The precision leaves much to be desired, but it is believed that the error probably does not exceed 20 pct.

#### Effect of Alloying Constituents

The effect on the solubility of nitrogen in austenite of the amounts of carbon, manganese, sulphur, and phosphorus usually present in plain low carbon steels is seen from Table II to be negligible. The effect of increasing amounts of manganese is shown in Table III. Up to 1.5 pct Mn, the effect is seen to be well within the error of analysis; from the previous data on time required (allowing for decreased thickness) as well as the agreement of the 6 and 16 hr specimens, there seems little doubt that these specimens were equilibrated with the atmosphere. The 13 pct Mn steel unquestionably absorbed considerably more nitrogen except at the highest temperature; no checks were run to determine whether it would have absorbed still more in longer time. Since 1.5 pct Mn does not observably affect the solubility and since

the effect of high manganese appears to decrease with temperature, it was thought that there might be a nitride precipitate in the high manganese steel. However, metallographic examination disclosed a completely austenitic structure free of observable precipitate.

The effect of silicon on the solubility of nitrogen is shown in Table IV. At each temperature the nitrogen content was lowered slightly by silicon. Difficulty was experienced in equilibrating higher silicon steels with the nitrogen atmosphere; for example a specimen of a 1.2 pct Si steel (a member of the series tabulated) contained 0.016 pct N after 89 hr treatment at 1046°C, and a similar specimen contained only 0.009 pct N after the longer treatment of 157 hr. A dynamo grade steel (3.48 pct Si) behaved even more erratically. The highest nitrogen content attained was 0.012 pct at 1203°C; this steel, however, is partially ferritic. It seems probable that this difficulty is due to an oxide film in spite of the aforementioned precautions and the fact that such film was not directly observable in the case of specimens cooled in the head of the furnace. Such difficulty was avoided by using a higher hydrogen content and higher temperature, which procedure places the series in the  $\delta$  region beyond the range of the present report.

### Precipitation of Aluminum Nitride

To investigate the effect of small amounts of per cent Al, principal use was made of steels from a series of ingots from the same heat (Nos. 3, 4, 5, 6, 8, and 11 of Table I); the aluminum addition was 0,  $\frac{1}{4}$ ,  $\frac{1}{2}$ , 1, 2, and 4 lb per ton, respectively. A few other aluminum-killed steels were also used. The nitrogen content of all samples treated above 1000°C is given in Table V. Equilibrium is believed to have been substantially attained in at least one run for each specimen at each temperature. This statement is based on checks of shorter and longer time runs or comparison of the time requirement with Fig. 1 (noting agreement of shorter time runs), taking into account any difference in thickness and the extra nitrogen absorbed; millings were used in two cases to hasten equilibrium.

The equilibrium nitrogen content is plotted against aluminum in Fig. 4. At each temperature the nitrogen content was independent of aluminum up to a critical amount thereof, above which the nitrogen rose abruptly. The small amount of aluminum present would not in any case be expected to influence observably the solubility of nitrogen in homogeneous austenite; the behavior of the lower aluminum specimens particularly at higher temperature verify this expectation. The abrupt rise in nitrogen content at higher aluminum is typical of the behavior encountered in the case of a phase change. If such is the case then this straight rising line is a tie line connecting the compositions of the two phases in equilibrium and should have a slope equal to the ratio of nitrogen to aluminum in the new phase.<sup>†</sup> The observed slope corresponds, well within the experimental error,<sup>‡</sup> to a one to one atom ratio of nitrogen to aluminum. Since the only known nitride of aluminum<sup>9, 10</sup> corresponds to the chemical formula AlN,

<sup>†</sup> Strictly, the slope is the ratio of the difference of nitrogen and of aluminum in the two phases, but as both are so small in the austenite there is negligible error in the above statement.

<sup>‡</sup> The experimental error is believed to be principally in the analytical determination of aluminum. The analyses here reported and used were performed in this Laboratory, and the precision as judged by checks and prior experience is about 0.003 pct. Check analysis by an outside laboratory varied by twice this amount.

Fig. 4—Nitrogen content of aluminum-killed steels equilibrated with nitrogen gas.

it seems almost certain that it is the precipitation of this phase which gives rise to the nitrogen contents (Fig. 4) which are in excess of the solubility in austenite; the lines of the figure are drawn with this theoretical slope.

The equilibrium constant (solubility product) for the reaction:

may be determined from the position of the break in each curve of Fig. 4. This point corresponds to the composition of austenite in equilibrium with AlN. The values of  $K$  (which is [pct Al] [pct N]) thus found are plotted against the reciprocal of the absolute temperature in Fig. 5. The line drawn may be represented by the relation:

$$\log K = -\frac{7400}{T} + 1.95$$

The heat of formation of AlN from dissolved nitrogen and aluminum is thus found to correspond to  $\Delta H = -34,000$  cal. This heat may also be estimated from Kelley's compilation,<sup>9</sup> in which, for the formation of AlN from metallic aluminum and gaseous nitrogen,  $\Delta H$  is selected as  $-54,700$  cal (at 1200°C); the data reviewed exhibit discrepancies of over 10,000 cal. Subtracting from this  $\Delta H = -500$  cal for the solution of nitrogen gas in austenite, and  $\Delta H = -15,000$  for the solution of aluminum in ferrite<sup>11</sup> at 20°C (which is here considered to apply approximately to aluminum in austenite at 1200°C), the computed value for  $\Delta H$  of formation of AlN from aluminum and nitrogen dissolved in austenite is

Fig. 5—The solubility product of aluminum nitride in  $\gamma$  iron.

Fig. 6—Aluminum-killed steel (0.144 pct Al) held in nitrogen for 93 hr at 923°C.

Aluminum nitride precipitate and grain refinement in rim zone permit its recognition even by naked eye. Rim-core boundary is indicated by arrows. Picral etch, X18.

Fig. 7—Same specimen as Fig. 6. Rim-core boundary at X65.

found to be  $-39,200$  cal, as compared to the above experimental value of  $-34,000$  cal. The discrepancy is within the many errors involved in the two determinations and lends support to the foregoing general interpretation of our results.

Several of the specimens of Table V, as well as some treated at 923°C, were examined metallographically. Specimens containing 0.047 and 0.144 pct Al, for which the time of treatment at 923° and 1048°C was insufficient to achieve complete equilibrium, exhibit a definite "rim" and "core" which

Rim

Core

Fig. 8—Same specimen as Fig. 6. Rim and core at X650.

were obvious, on the polished sample, even to the naked eye. Examination of the specimens disclosed that the rim differs from the core in two distinct respects: 1—the rim contains a copious fine precipitate which the core does not; 2—the ferrite grain size of the rim was considerably smaller (by about 2 A.S.T.M. sizes) than that of the core. Obviously, the nitride here forms a subscale similar to that found, for example, by Rhines<sup>12</sup> in the case of some oxides. The difference between the subscale (rim) and central (core) zones is illustrated for a typical specimen by the micrographs of Figs. 6 to 8. Even at X650 (Fig. 8) the precipitate is barely resolvable. However, it is shown clearly in the electron micrograph of Fig. 9.

Subscale thickness for a few specimens is given in Table VI. The fact that precipitation occurred throughout one specimen furnishes added evidence that this specimen (the composition of which is used in Fig. 4) is substantially equilibrated with the atmosphere. The final entry in the table is for a specimen in which the subscale has penetrated 90

Rim

Core

Fig. 9—Same specimen as Fig. 6. Electron micrograph at X9000 of rim showing aluminum nitride precipitate and core.

Table VI. Subscale Thickness

| Temperature, °C | Pct Al | Time of Treatment, Hr | Pct N | Subscale Thickness, Mm |
|-----------------|--------|-----------------------|-------|------------------------|
| 923             | 0.047  | 40½                   | 0.021 | 1.0                    |
|                 | 0.144  | 40½                   | 0.036 | 0.5 <sub>s</sub>       |
|                 | 0.144  | 93                    | 0.051 | 0.7 <sub>s</sub>       |
| 1048            | 0.047  | 21                    | 0.033 | 1.4 <sub>o</sub>       |
|                 | 0.047  | 65                    | 0.048 | (Complete)             |
|                 | 0.144  | 21                    | 0.045 | 0.65                   |
|                 | 0.144  | 65                    | 0.080 | 1.7 <sub>o</sub>       |

pct of the way to the center; this is in rough agreement with what would be expected by comparing its nitrogen content (0.080 pct) with that (0.091 pct) of the equilibrated milled specimen of Table V.

In general, the observed subscale thickness is somewhat less than the thickness computed from the diffusivity on the assumption that the surface of the specimen is saturated with nitrogen. This is not surprising since it has been shown, Fig. 3, that surface saturation is not achieved in this temperature range. It may be worthy of comment that in one case (the final entry of Table VI) the subscale or zone of precipitation extended much further than the zone of fine grains. This may be associated with the fact that aluminum nitride is by no means "insoluble" and hence the transition from rim to core is not sharp. Grain refinement undoubtedly depends on the number and size of the precipitated particles both of which vary somewhat. However, in all other cases, within the error of measurement, the grain size change occurred at the inner boundary of the subscale.

#### Summary

The solubility of nitrogen gas in iron and low alloy steels has been measured in the  $\gamma$  region from 930° to 1350°C. The specimens were equilibrated

with the gas and analyzed. The diffusivity of nitrogen in iron is reported at 955° and 1348°C ( $D = 1.9 \times 10^{-7}$  and  $3.1 \times 10^{-6}$  sq cm per sec, respectively). The solubility in plain low carbon steels is the same as that in iron and may be represented by the equation:

$$[\text{Pct N}] = 0.0404 - 1.2 \times 10^{-5} T$$

Manganese up to 1.5 pct has no observable effect. Silicon (0.58 pct) appears to lower the solubility slightly. Steels killed with sufficient aluminum exhibit a precipitate of aluminum nitride (AlN) which, for incompletely equilibrated specimens is in the form of a subscale. The solubility product of aluminum nitride has been determined. This solubility product or equilibrium constant may be represented by the relation:

$$\log K = \log [\text{Pct Al}] [\text{Pct N}] = -(7400/T) + 1.95.$$

#### Technical Note

### Change in Yield Strength During Aging in Iron

by C. A. Wert

THE change in mechanical properties accompanying quench aging of carbon in  $\alpha$  iron has been known for a number of years. Since the amount of carbon involved is rather small, however, no measurements could be made to correlate the property change with the state of precipitation of the carbide. Indeed, until a few years ago it was not plain which property might be used to indicate the state of the progress of precipitation. Some years ago the internal friction of solid solutions of carbon in  $\alpha$  iron was demonstrated, and the use of this phenomenon to ascertain the amount of carbon in solid solution

at any given time was developed. Shortly afterward the author made a number of measurements in which changes in electrical resistance, thermoelectric emf, and hardness were determined simultaneously with the internal friction (and hence with the precipitation).<sup>1</sup> A little later Dijkstra and Wert measured the change in magnetic coercive force accompanying aging.<sup>2</sup>

The present work was undertaken to inquire into the changes in yield strength accompanying aging. The work was done on specimens made of Puron. These specimens were 0.05 in. in diam and about 6 in. long. Though specimens of this small size are not ideal for yield strength measurements, such specimens are desirable for internal friction meas-

Fig. 1—Change in yield strength accompanying precipitation of carbide in  $\alpha$  iron.

urements. The tensile machine used was essentially the same as that used previously by the author in a similar type of investigation.<sup>8</sup> Specimen grips were made which would fit into both the torsion pendulum apparatus and the load bearing supports of the tensile machine. These grips were silver soldered to the ends of the specimen. Numerous attempts were made to attach the grips after all heat treatments (decarburization, carburization, and aging) just prior to the tensile measurement, but these attempts were all futile because the soldering operation invariably produced softening sufficient to cause failure of the sample at the grips. By soldering the grips in place before these heat treatments however, this was avoided except for an occasional sample which had a very high yield strength. Elongation of the sample during loading was measured by running a single strand of 0.001 in. resistance wire along a 2 in. section in the center of the sample. This strain-gage wire served as one arm of a Wheatstone bridge.

Measurements were made on three groups of samples; these groups were aged at 40°, 65°, and 130°C, respectively, after having been carburized to about 0.015 pct C. The yield strength data and the precipitation data (the latter as deduced from internal friction measurements) are shown in Fig. 1. The significant points to be noticed are:

Table I. Calculation of Particle Diameter for Fully Aged Specimens

| Temperature, °C | $d$ (Angstroms) | $d'$ (Angstroms) |
|-----------------|-----------------|------------------|
| 40              | 160             | 1000             |
| 65              | 210             | 1300             |
| 130             | 500             | 3000             |

1—The peak yield strength becomes higher as the aging temperature is lowered. This was perhaps to be expected from previous knowledge of behavior of hardness during quench aging.

2—The increase in yield strength occurs simultaneously with the precipitation. The peak is not reached until near the end of the precipitation process, after which the decline in yield strength is fairly rapid. Overaging is seen to manifest itself in yield strength just as it does in hardness. It is not clear from these measurements (nor does it seem clear from any other measurement) what is the detailed mechanism of overaging.

By methods previously described,<sup>1</sup> a calculation of particle diameter,  $d$ , for fully aged specimens (and hence of mean particle distance,  $d'$ ) was made.<sup>1</sup> These calculations give the results shown in Table I.

Fig. 2—Change in various properties during aging of carbon in iron at 100°C.

This plot represents yield strength, hardness, and coercive force measurements at 20°C; internal friction at 40°C; electrical resistance at -195°C; and thermoelectric emf (relative to decarburized iron) between -195° and 0°C.

If the peak yield strength be plotted as a function of  $\log d'$  (after Gensamer, Pearsall, Pellini, and Low<sup>4</sup>) a straight-line function is obtained though with a much different magnitude and slope from the work of Gensamer et al.

This measurement adds to the growing list of physical properties that have been correlated to the precipitation of carbide in  $\alpha$  iron. Fig. 2 shows schematically how these properties change during a typical heat treatment at, say, 100°C. With the exception of magnetic coercive force, where a striking critical-size-effect was observed, all these properties change steadily during the precipitation, the major change in property coming during the most rapid formation of the carbide.

# Effect of Varying the Rate of Reduction on the Magnetic Properties, Ultimate Tensile Strength, and Resistivity Of 18/8 Stainless Steel Wire

by Samuel Storchheim

IT was noted that variations existed in the magnetic properties, namely, coercive force,  $H_c$ , and remanence,  $B_r$ , of 18/8 stainless steel wires of the same analysis when these wires were given the same percentage of reduction of area at different rates of reduction. In order to determine the extent of these variations, a program was initiated whereby commercial 302 and 304 stainless steels were drawn with a wide variation of speeds. Ultimate tensile strengths and specific resistances, as well as the  $H_c$ - $B_r$  measurements, were determined. If variations of considerable magnitude were found, it was thought that the knowledge accrued from the investigation could probably aid in determining the particular drawing speed required to obtain desired properties for a given specification for a particular analysis of wire.

## Drawing Procedure

Two specimens (set I, No. 302 and No. 304), the chemical analyses of which are given in Table I, were drawn at different speeds, namely, 45 to 3900 ft per min, directly from 0.016 in. diam wire to 0.004 in. diam wire, a 93.7 pct reduction of area. To obtain this high percentage of reduction, the wire at 0.016 in. was softened by annealing at 1150°C. It was then strung in a No. 16CF variable speed Vaughn drawing unit and passed through 13 B.&S. gage dies of successively smaller diameter, as shown in the accompanying table.

Following this step, several hundred feet of the wire was drawn, at a particular speed, through the dies and wound upon a spool. Once the sample of wire was drawn at the desired speed, the spool with the finished sample was removed, tagged for later identification, and an empty spool was placed in the machine. Another wire sample was drawn at a different speed, after making the necessary adjustments upon the Vaughn unit. At the greater speeds, several thousand feet of sample were drawn to insure that the wire to be used for testing would be uniform. This was done because the desired speed was not reached instantly; the wire taking a short while to attain the required drawing rate. All speed measurements were made by placing a tachometer against one of the machine's pulleys during the actual drawing of the specimens.

S. STORCHHEIM, formerly Metallurgical Engineer, Wilbur B. Driver Co., Newark, N. J., is now Senior Metallurgical Engineer, Metallurgical Laboratories, Sylvania Electric Products Inc., Bayside, N. Y.

Discussion on this paper, TP 3181E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, June 15, 1951; revision, Aug. 3, 1951. New York Meeting, February 1952.

To broaden the extent of the investigation, two additional specimens (set II, No. 302 and 304), analyses for which are given in Table I, were studied for variations in properties. However, these were drawn at heavier starting sizes directly through nine dies in a 12 HF Vaughn wire drawing unit. The B.&S. gage numbers and die diameters used were as given in the accompanying table which shows an

84.4 pct reduction of area. The 0.072 in. diameter wire was also annealed at 1150°C. The process of obtaining samples was the same as described above. The only difference between the two was that the rates involved were not as extensive, set II covering a range of 625 to 1150 ft per min.

Tensile tests were carried out for the 0.004 in. diam wires on a horizontal Scott Tensile Tester, while tensile tests for the 0.028 in. diam wires were made on a vertical Scott Tensile Tester. Each value listed in the tables represented the average of five samples with a maximum deviation of approximately 3 pct among the samples. Resistance per foot of the wires was determined by use of standard bridges accurate to the nearest hundredth of an ohm for the 0.004 in. wire, and to the nearest thousandth of an ohm for the 0.028 in. wire. The resistances per foot were then converted to resistivities by use of the following equation:

$$P = R \times CM$$

where  $R$  is the resistance per ft in ohms per ft;  $CM$ , the area in circular mils; and  $P$ , the resistivity in ohms- $CM$ . The values listed in the tables likewise

ft

represented the average of five samples among which there was a maximum deviation of about 2 pct.

The magnetic measurements,  $H_c$ - $B_r$ , were made with a Hysteresis Loop Tester<sup>1</sup> which projected the

Fig. 1—Coercive force as a function of speed of draw for set I.

Fig. 2—Remanence as a function of speed of draw for set I.

image of the hysteresis loop on a previously calibrated cathode ray oscilloscope screen. The results obtained were the average of five samples with a maximum deviation of 5 pct for the  $H_c$  readings and 10 pct for the  $B_r$  readings.

The data obtained using these sets of stainless steel types are tabulated in Tables II to V, and from these tables curves were drawn depicting the general nature of the various relationships between the log of the rate of reduction vs. other properties, Figs. 1 to 4.

### Discussion of Results

**Rate of Reduction vs. Coercive Force:** For set I, the two analyses exhibited similar coercive force curves with the exception that they were displaced from each other, see Fig. 1. For the 302 analysis, the curve indicated that the  $H_c$  values were low at low rates of draw, but rose quickly at moderate rates of

draw to a value approximately 143 pct greater than that initially obtained. Once this "ultimate" value was obtained, there was little deviation from it except that caused by scatter. The 304 curve showed an initially lower  $H_c$  value than the 302 curve at low speeds. This value also rose as did the 302 curves, but more slowly. As in the case of the 302 curve, the final  $H_c$  of the 304 curve increased over its initial value by approximately 143 pct.

The limited spread of rates of reduction for set II did not warrant a similar plotting. However, these data plus those of set I indicated that an increase in the percentage of nickel content caused an upward displacement in the relative positions of curves; i.e., the  $H_c$  was increased for the same speed of draw when the nickel content was higher.

**Rate of Reduction vs. Remanence:** When the remanence curves for the two analyses of set I were plotted, they did not follow similar patterns as was the case with the coercive force curves, see Fig. 2. The 302 curve indicated a high  $B_r$  value at low drawing speeds which gradually fell off at increasing speeds and then levelled off at high rates of draw and remained relatively constant as in the case of the  $H_c$  values. The 304 curve behaved differently in that the initial values of  $B_r$  at low drawing rates were low. As the rates increased these values increased and then decreased gradually.

The data from set I together with that from set II indicated that higher nickel contents at moderate-to-fast rates of draw exhibited lower values of  $B_r$ . However, set I showed that the higher nickel 302 at slow rates of draw exhibited values of  $B_r$  about 45 pct greater than the lower nickel 304, in fact 9 pct higher than any other obtained with the lower nickel analysis regardless of drawing speed. The variation of  $B_r$ , within the higher nickel (set I, 302) specimens, was greater over the range of drawing speeds investigated than the lower nickel (set I, 304), namely, 51.0 pct as against 27.2 pct, respectively.

**Rate of Reduction vs. Ultimate Tensile Strength:** Plotting the ultimate tensile strengths of both the 302 and 304 vs. the rate of reduction gave two curves similar in appearance, but, as in the  $H_c$  set, dis-

placed from each other, see Fig. 3. Initially, the values were high at slow drawing rates but decreased gradually to a value which remained relatively constant from moderate to very fast drawing rates; i.e. constant from about 200 ft per min up to 3900 ft per min. The maximum decrease in tensile strength obtained at fast rates of draw for the "constant" tensile value over the initially high (slowest speed of draw) value was approximately 6 pct for the 302 and 4 pct for the 304. In the cases investigated the higher carbon 302 specimen of both sets I and II exhibited the higher tensile values, about 4 pct higher for set I and 10 pct higher for set II. The low carbon content 304 tensile value at 50 ft per min was equivalent to the higher carbon containing 302 drawn between 300 and 3900 ft per min. The low tensile value obtained for the 302 curve at 100 ft per min was believed caused by a possible improper sampling; i.e., sufficient wire may not have been drawn to obtain a true representation of that particular drawing speed. The "dips" in the two curves at 2000 ft per min possibly were the results of a mechanical fluctuation of the drawing unit while the wire was being drawn.

**Rate of Reduction vs. Resistivity:** The resistivity/rate curves generally were not too alike except that they showed a trend to decrease as the speed increased, see Fig. 4. For the 302 curve of set I, the strongly decreasing trend stopped at about 300 ft per min where the resistivity partially levelled off to a slowly decreasing value. Between 50 to 300 ft per min a maximum drop of 10 pct was experienced. The curve for 304 of set I showed a gradual decrease through the entire range of speeds investigated. The maximum decrease in resistivity obtained again was about 10 pct. In both sets of curves, the highest values of resistivity were found at the slowest drawing speeds.

Using both groups of data from sets I and II, it was seen that the resistivities were lowered by an increase in nickel content; i.e., for the same rate of drawing speed, an analysis of higher nickel content exhibited a lower specific resistance. The lower nickel 304 curve of set I at very slow rates of draw exhibited a value of resistivity approximately 10 pct greater than the higher nickel 302 for the same low rate of draw, namely, 50 ft per min. A maximum difference of almost 20 pct was obtained between the two analyses over the range of speeds investigated.

### Explanation of Effects of Drawing Speed

A possible explanation of the effects found on the properties of 18/8 stainless steel by varying the rate of drawing speed could be as follows: Cold working a metastable austenitic 18/8 stainless steel produces martensite, provided the temperature during work-

Fig. 3—Ultimate tensile strength as a function of speed of draw for set I.

Fig. 4—Resistivity as a function of speed of draw for set I.

ing is not much higher than room temperature.<sup>2</sup> During the process of drawing wire through a die or a series of dies, an increase in temperature of the wire occurs, because of the dual processes of deformation and friction. The wire generally will be cooled off by the coolant to approximately room temperature in the time that it travels the distance from one die to the next. Should the temperature become greater, less martensite will be formed. Thus, if the speed of draw is increased to the point where the lubricant can no longer cool the wire fast enough, the temperature of the wire will rise above the room temperature. Therefore, the higher the drawing speed, the higher the temperature, and less martensite will be formed; consequently, the *Br*, resistivity, and tensile strength will be lower and the *Hc* will be higher.

### Conclusion

It was determined that variations did exist in magnetic properties, ultimate tensile strength, and specific resistance of commercial 18/8 stainless steel wires when the rate of reduction of these wires was varied. With increasing drawing rates it was found that coercive force increased, while remanence, tensile strength, and resistivity decreased. The changes in coercive force and remanence were quite extensive, while those of tensile and specific resistance, although significant, were less. A higher nickel content caused, for the same rate of draw, an increase in *Hc* and a decrease in *Br* and resistivity. Higher carbon contents exhibited higher tensile values for the same rate of draw.

From the above results and by possible further future investigation, it would appear that an 18/8 stainless steel analysis, which might normally have been considered inferior for a particular specification, could be salvaged by the correct choice of drawing speed. This could be of special value when the present critical situation regarding the availability of almost all metals and alloys is considered.

# Correlation Between Electrical Conductivity and Temperature

## Coefficient of Resistance of Solid-Solution Alloys

by M. Hansen, W. R. Johnson, and John M. Parks

AS part of a research project sponsored by the Signal Corps Engineering Laboratories, which had the objective of obtaining a magnet wire of good conductivity and low temperature coefficient of resistance, a comprehensive literature survey, supplemented by experimental work, revealed that a linear relationship exists for solid-solution alloys between the electrical conductivity,  $\kappa$ , and the temperature coefficient,  $\alpha$ , as expressed by the equation:

$$\kappa = \alpha\beta$$

where  $\beta$  is constant for the solvent metal and  $\alpha = \frac{\Delta R}{\Delta t R_0}$  per °C.

It has long been known that the electrical conductivity at a given temperature and the temperature coefficient of resistance of binary alloys are related to their constitution by the LeChatelier-Guertler rules, as illustrated by Figs. 1 and 2:

Rule 1—In alloy systems consisting of a heterogeneous mixture of two phases, the electrical conductivity and temperature coefficient vary as a straight line, if the composition of the alloys is given in volume percentage, Fig. 1.

Rule 2—In solid solutions, the electrical conductivity and temperature coefficient are always lower

than those of the solvent metal, and usually a considerable decrease occurs with the first small percentage additions of the solute metal, Fig. 2b. If the two components form a continuous series of solid solutions, the electrical conductivity and temperature coefficient curves take the form of a U-curve, Fig. 2a.

That some kind of proportionality exists between electrical conductivity and temperature coefficient of resistance is implied by the LeChatelier-Guertler rules and by study of data such as those given by Smith and Palmer,<sup>1</sup> Fig. 3. Dellinger<sup>2</sup> in 1910 first recognized this relationship in a number of commercial copper wires, ranging in conductivity from 94 to 100.7 pct I.A.C.S. He gave the ratio of temperature coefficient to the percentage of conductivity as a constant,  $C = 0.003939$ . A year later, Lindeck<sup>3</sup> observed that the linear relationship was valid for a wider range of conductivity in "various sorts of copper," and concluded that the product of resistivity and temperature coefficient was  $6.78 \times 10^{-5} \pm 1.5$  pct. Since then, this relationship seems to have been entirely ignored.

### Conductivity-Temperature Coefficient Relationship

If the electrical conductivity of copper solid-solution alloys with phosphorus, silicon, arsenic, antimony, aluminum, nickel, manganese, and iron is plotted against the temperature coefficient of these alloys, the diagrams in Figs. 4 and 5 are obtained. Similar data were found with copper-rich solid solutions containing magnesium, cobalt, and titanium,<sup>13</sup> as shown in Fig. 6. In all cases, a linear relationship exists. The point representing the highest

Discussion on this paper, TP 3189E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, July 12, 1951. New York Meeting, February 1952.

Figs. 1 and 2—Electrical conductivity of binary alloy vs. constitution.

conductivity and temperature coefficient is that of pure copper; as increasing percentages of solute elements are added, both the electrical conductivity and the temperature coefficient of resistance decrease along the straight line, until the solubility limit is reached. Beyond that composition, a deviation from the straight line results as illustrated by the Cu-P and Cu-Al data presented in Figs. 4 and 5.

If the low conductivity end of these plots is examined in detail, it may be seen that, in the case of the solid solutions with phosphorus, arsenic, and antimony, the extrapolated line almost intersects the origin of the plot. With Cu-Si and Cu-Al solid solutions, the straight line cuts the abscissa slightly to the right of the origin; whereas with Cu-Ni, Cu-Mn, and Cu-Fe, it cuts the abscissa to the left of the origin, nickel, manganese, and iron being transition elements. However, with all of these addition agents to copper, there is no appreciable deviation from the straight line conductivity vs. temperature coefficient of resistance relationship except for the low conductivity, low temperature coefficient range of Cu-Mn and Cu-Ni solid solutions. In Cu-Mn solid solutions, a negative temperature coefficient of resistance is reached between 4.5 and 9.5 pct Mn, Fig. 3.

Copper and nickel form a continuous series of solid solutions. According to Feussner and Lindeck,<sup>21</sup> the temperature coefficient becomes negative between 30 and 40 pct Ni and, with increasing nickel contents, positive again between 46 and 49 pct Ni. This finding agrees with that of Smith and Palmer, Fig. 3, who found that a negative temperature coefficient will be attained at about 33 pct Ni. On the

Fig. 3—Electrical conductivity and temperature coefficient of resistance of Cu-Mn and Cu-Ni solid solutions.

Fig. 4—Electrical conductivity vs. temperature coefficient of resistance of solid solutions of copper with phosphorus, silicon, arsenic, and antimony.

other hand, Krupkowski<sup>10</sup> found a negative temperature coefficient around 45 pct Ni. As the nickel content is increased further, the conductivity vs. temperature coefficient plot follows a curve which approaches the point representing pure nickel ( $\kappa_{20^\circ\text{C}} = 14.62$ ;  $\alpha_{0-100^\circ\text{C}} = 0.0069$ ).<sup>14</sup> As shown in Fig. 5, this curve is not a straight line, probably because alloys with more than 69 pct Ni are ferromagnetic at room temperature. The temperature coefficient curve for the Cu-Ni system, as determined by Krupkowski,

Fig. 5—Electrical conductivity vs. temperature coefficient of resistance of solid solutions of copper with aluminum, nickel, manganese and iron.

shows a large deviation from the ideal U-curve in this composition range, which indicates that the temperature coefficient is considerably affected by the electronic transitions which produce ferromagnetism.

Fig. 6 summarizes the data on various copper-base solid solutions plotted on the same basis; it indicates a slight spread in the data for these alloys. This linear relationship also holds for ternary copper-base solid solutions, Fig. 7, as well as for silver-base and gold-base solid solutions, Figs. 8 and 9. Furthermore, all data available on solid-solution additions to other metals, such as aluminum, magnesium, zinc, platinum, palladium, tin, lead, molybdenum, and tungsten, indicate that this linear relationship is a fundamental property of solid-solution conductors.

It appears justified, therefore, to draw a conductivity vs. temperature coefficient of resistance curve for the various solvent metals, such as shown in Fig. 10. The slope,  $\beta$ , of each of these straight lines gives a constant which is a characteristic of the solvent metal, as indicated in Table I.

The capacity of each metal to form solid solutions with other metals, and their specific influence on the

Fig. 6—Electrical conductivity vs. temperature coefficient of resistance of binary copper-base solid solutions.

Fig. 7—Electrical conductivity vs. temperature coefficient of resistance of ternary copper-base solid solutions.

electrical properties of the base metal determine how far the straight line for the respective binary, ternary, or more complex solid solutions extends from the point representing the pure solvent metal toward the point of origin of the diagram. The linear plots of Fig. 10 should be considered for approximate purposes only, especially in the low conductivity-low temperature coefficient range, as slight deviations occur for certain solute metals as indicated by Fig. 6. A slight deviation will also occur in solid solutions which undergo a magnetic transformation, as shown for the nickel-rich Cu-Ni solid solutions, Fig. 5.

The existence of the linear correlation between electrical conductivity and temperature coefficient of resistance of solid-solution alloys provides a simple means to predict, within certain limits, temperature coefficients of any single-phase alloy if the conductivity is known, and vice versa. Or if it is desired to achieve a certain electrical conductivity and corresponding temperature coefficient in a given base metal, a large number of alloying components may be used. For example, to achieve 60 pct of the conductivity of standard copper, and its corresponding temperature coefficient of 0.0023 per °C,

the various elements listed in Table II can be added to copper in the percentages indicated. Or to obtain the same conductivity, and the corresponding temperature coefficient of 0.0021 per °C for a silver-base alloy, various elements in the percentages also given in Table II may be added to silver.

### Linear Relationship in Binary Systems

For binary systems with a continuous series of solid solutions, two straight lines are found when the conductivity is plotted against the temperature coefficient. Fig. 11 shows such diagrams for the systems

Fig. 9—Electrical conductivity vs. temperature coefficient of resistance of binary gold-base solid solutions.

Fig. 10—Electrical conductivity vs. temperature coefficient of resistance of solid solution alloys with various elements as base metals.

Ag-Pd, Au-Pd, and Pd-Pt, based on the data given by Geibel.<sup>17-19</sup> The two branches of the Ag-Pd and Au-Pd alloys represent the conductivity vs. temperature coefficient plot of the silver-rich and gold-rich solid solutions, on one hand, and the palladium-rich solid solutions, on the other. The point of intersection represents—considering possible experimental errors—approximately 50 atomic pct; the actual atomic percentage of palladium of the alloys is indicated beside each point on the diagram. The lines representing the silver-rich and gold-rich solid solutions intersect very close to the origin, whereas the extrapolation of the line representing the palladium-rich solid solutions cuts the abscissa to the left of this point. This may be related to the fact that palladium is a transition metal. Both branches of the conductivity vs. temperature coefficient plot of Pd-Pt solid solutions practically coincide, since the conductivity and temperature coefficient of pure palladium and platinum are almost identical. Again, the lowest point of the plot is about 50 atomic pct.

For binary alloy systems in which the component metals are soluble in each other to a limited extent and do not form an intermediate phase, the conductivity-temperature coefficient diagram consists of

Fig. 11—Electrical conductivity vs. temperature coefficient of resistance diagrams of the systems Ag-Pd, Au-Pd, and Pd-Pt.

two straight lines representing the electrical properties of the primary solid solutions and a third straight line joining the points representing the saturated solid solutions for each phase. This is illustrated in Fig. 12 by data for the Cu-Co<sup>20</sup> and Cu-Ag<sup>21</sup> systems.

### Norbury and Kuwada Relationship

Norbury and Kuwada<sup>5</sup> tried to find a correlation between electrical resistivity and temperature coefficient of resistance of copper-base alloys. The temperature coefficient they used was defined as  $\alpha' = \frac{\Delta R}{\Delta t}$ , rather than as  $\alpha = \frac{\Delta R}{\Delta t R_0}$ , which is normally used. On the basis of resistivity measurements of copper alloys containing aluminum (up to 3.8 pct), tin (up to 3.9 pct), and silicon (up to 2.7 pct) at various temperatures between  $-191^\circ$  and  $438^\circ\text{C}$ , they claimed that a linear relationship between resistivity at  $0^\circ\text{C}$  and  $\alpha' = \frac{\Delta R}{\Delta t}$  (for that temperature range) exists, which may be expressed by the equation:

$$\alpha' = (0.0064 + R_0 \times 0.0002) \text{ microhms-cm per } ^\circ\text{C} \quad [1]$$

Their data are shown in Fig. 13, together with those of some Cu-Ni and Cu-Mn solid solutions. The values for the latter do not follow the linear correlation, as their resistivity does not change linearly between  $-191^\circ$  and  $438^\circ\text{C}$ .

In order to throw further light on Norbury and Kuwada's relationship, data obtained by other authors have been similarly evaluated. Fig. 14 shows

resistivity vs.  $\frac{\Delta R}{\Delta t}$  based on data by Smith and Palmer<sup>2</sup>; the  $\frac{\Delta R}{\Delta t}$  values were calculated using re-

sistivity values for  $20^\circ\text{C}$  and  $\alpha = \frac{\Delta R}{\Delta t R_{20^\circ\text{C}}}$  values de-

termined from resistivity data at  $200^\circ$  and  $20^\circ\text{C}$ . It follows from Fig. 14 that the curves for Cu-Si and Cu-Al solid solutions deviate substantially from each other, and do not obey the relationship of eq 1. The solid solutions with the transition elements manganese and nickel behave very differently; with

relatively low nickel contents, the  $\frac{\Delta R}{\Delta t}$  values are

Fig. 12—Electrical conductivity vs. temperature coefficient of resistance diagrams of the systems Cu-Co and Cu-Ag.

somewhat larger, and above 20 pct Ni they become smaller, than that of pure copper.

In a similar way, data given by Linde<sup>7</sup> have been evaluated; the  $\frac{\Delta R}{\Delta t}$  values were based on resistivities at  $-183^\circ$  and  $0^\circ\text{C}$ . The results for the solid solutions with arsenic and antimony did not obey Norbury and Kuwada's relationship. Again, the alloys with manganese, and also with iron, behave quite differently, although their temperature coefficient of resistance is constant between  $-183^\circ\text{C}$  and room temperature.

In general, it can be said that eq 1 does not hold for all copper-base solid solutions, even if the transition elements are excluded as solvents. Hence, this relationship cannot be regarded as a means of predicting resistivity of copper-rich solid solutions if  $\frac{\Delta R}{\Delta t}$  is known, and vice versa. On the other hand, the linear relationship between electrical conductivity and the temperature coefficient of  $\alpha = \frac{\Delta R}{\Delta t R_0}$  essentially holds for all solid-solution alloys, regardless of the base metal.

### Conclusions

1—A linear relationship has been found to exist between the electrical conductivity and temperature coefficient of resistance ( $\alpha = \frac{\Delta R}{\Delta t R_0}$ ) for all solid-solution components added to a given metal solvent.

2—Each solvent metal has its own distinctive  $\beta$  value—defined as the slope of the electrical conductivity-temperature coefficient of resistance plot.

3—Of the common metals, the  $\beta$  value is highest for silver, and progressively smaller for copper, gold, aluminum, magnesium, zinc, platinum, nickel, tin, iron, and lead.

4—Knowledge of this relationship permits quick approximation of the temperature coefficient of resistance of a solid-solution alloy by measurement of its conductivity, or vice versa.

# Metallurgical Mechanism for Mercury Stress Cracking Of Copper Alloys

by W. D. Robertson

SINCE the comprehensive paper of Moore, Beckinsale, and Mallinson,<sup>1</sup> little consideration has been given to the mechanism of mercury stress cracking of copper-base alloys, apart from extensive work on metallurgical and fabrication variables employing mercurous nitrate as an evaluation test. However, with the phase diagrams now available and the recent considerations of interfacial tension at grain boundaries, developed by Smith,<sup>2</sup> it appears that the elements of a detailed solution to the problem are available.

The facts that require explanation are:

1—Pure copper is not embrittled by mercury, with or without an applied or residual stress.

2—Cu-Zn and other copper-base alloys, in excess of some undefined solute concentration, are embrittled provided an external or residual stress is acting; cracking is not observed in the absence of stress.

3—The path of fracture is invariably intergranular.

4—Copper and copper-base alloys do not dissolve readily in mercury at room temperature.<sup>1</sup>

Consideration of the Cu-Hg phase diagram<sup>3</sup> shows that, at room temperature, solution of copper in mercury is probably limited by the formation on the surface of a microscopically thin layer of intermetallic compound, CuHg, having a very limited range of solubility which effectively restricts diffusion of copper and mercury. But, above 150°C (the highest peritectic temperature) copper solid solution is in equilibrium with a liquid Hg-Cu solution and, consequently, copper should dissolve freely in a large volume of mercury with the formation of an equilibrium dihedral angle at grain boundaries in contact with the liquid phase. Depending on the magnitude of this angle, mercury will or will not penetrate the solid phase along grain boundaries and spread over grain faces. Thus the measurement of the dihedral angle of grain boundaries in equilibrium with the liquid phase above 150°C should indicate whether copper is intrinsically resistant to embrittlement by mercury. In view of the fact that mercury is appreciably soluble in copper, it may also be anticipated that diffusion of mercury will take place at higher temperatures in the absence of the intermetallic compound and possibly at a more rapid rate along grain boundaries than through the grains, resulting in a Cu-Hg alloy of unknown properties.

In the case of brass, the ternary system Cu-Zn-Hg is involved and, from the resistance of brass to general solution in mercury at room temperature, it is probable that a compound of limited solubility range also exists, similar to the binary Cu-Hg sys-

Fig. 1—Copper annealed at 700°C, immersed in mercury at 170°C. X300.

Fig. 2—Brass (69 pct Cu) annealed at 850°C, immersed unstressed in mercury at 350°C. X150.

tem. Also, compared with copper, a change in the dihedral angle at grain boundaries in contact with mercury may be expected to result from the addition of zinc to copper. The preceding generalizations appear to be confirmed by the following experiments.

## Experimental Results

Oxygen-free copper wire, annealed at 700°C for 3 hr in copper foil, was immersed in mercury at 170°C, with and without an applied stress. After 24 hr immersion, specimens which were spring loaded to a nominal stress of 10,000 psi had not failed, and there was no apparent embrittlement as indicated by a 180° bend around a diameter approximately equal to the diameter of the wire (0.125 in.): General solution of the surface had taken place, indicated by a change in diameter of the wire, and the resulting structure of the surface is shown in Fig. 1. It is apparent that angles have developed at grain boundaries and examination at a high magnification indicates that the angle is in excess of 120°, completely excluding penetration of mercury. In view of the measurements made by Smith<sup>2</sup> on the

Cu-Pb system, it may be assumed that the dihedral angle does not vary greatly with temperature and, therefore, the value obtained at 170°C is applicable at room temperature. It may also be assumed that the applied stress will not appreciably affect the angle, and examination of both stressed and unstressed specimens indicates that the apparent angles are similar in both cases which is, in part, confirmed by the fact that none of the stressed specimens failed.

Brass sheet (69 pct Cu), after annealing at 850°C for 3 hr followed by slow cooling, was immersed, unstressed, in mercury at 170°C for 40 hr. A 90° bend at room temperature, after evaporation of the mercury at a low pressure, showed embrittlement at grain boundaries, but angles were not well developed and there was no significant general solution of the alloy. Consideration of the possible ternary system now involved indicated that a higher temperature might be required, and a second test was conducted, unstressed, at 350°C for 18 hr. Complete embrittlement resulted together with general solution of the brass. The microstructure, Fig. 2, reveals the cause of embrittlement. It is apparent that a layer of a second phase has formed, probably on cooling to room temperature, and the dihedral angle has changed from the large value characteristic of copper to something much less than 60° as a result of the addition of zinc to the alloy. Instead of the alloy dissolving in mercury with the formation of a large dihedral angle, extensive penetration of the grain boundaries by the phase present on the surface has taken place.

These experiments apparently lead to the following conclusions regarding the mechanism of stress cracking of copper-base alloys in mercury.

1—Copper is not susceptible to mercury cracking because the equilibrium dihedral angle formed at grain boundaries in contact with mercury is such that penetration is impossible.

2—Cu-Zn alloys, above some zinc concentration to be determined by quantitative measurement of the angles as a function of zinc concentration, may be embrittled by mercury because the dihedral angle formed by the solid solution and liquid mercury is less than 60° leading to penetration under equilibrium conditions and in the absence of an applied or residual stress.

3—At room temperature, equilibrium between brass and liquid mercury is not attained owing to the formation of an intermetallic compound which prevents continued penetration. If, however, an external or residual stress is present, the brittle compound formed at the surface is fractured allowing further contact of the alloy with mercury and continued penetration in accordance with the small dihedral angle.

Fig. 3 shows the initial stage in the fracturing of the brittle phase by bending the brass sheet after cooling to room temperature and evaporating mercury at a low pressure. Fig. 4 shows that a grain, which was surrounded at the higher temperature in the absence of stress, can be completely separated from the matrix by bending at room temperature. It is apparent that the path of fracture is through the brittle phase formed in the grain boundaries.

Thus the function of stress is apparently defined as a mechanical aid to the continued contact of the alloy with mercury. Basically, the problem is resolved in terms of the equilibrium dihedral angle. The limiting zinc concentration above which Cu-Zn alloys may be embrittled by mercury is, to a first

Fig. 3—Brass (69 pct Cu) annealed at 850°C, immersed unstressed in mercury at 350°C, and bent at room temperature after evaporation of mercury at a low pressure. Initial stage of fracture passing through brittle phase at grain boundaries.

Fig. 4—Brass (69 pct Cu) annealed at 850°C, immersed in mercury at 350°C, and bent at room temperature after removal of mercury by evaporation at a low pressure. Final stage of fracture passing through brittle phase at grain boundaries.

approximation, defined by the alloy in which the dihedral angle is less than 60°; measurements are now being made to determine quantitatively the equilibrium angle as a function of zinc concentration and temperature.

Mercury stress cracking appears, therefore, as a problem in interfacial tension and intermetallic compounds, and no special properties of grain boundaries need be invoked, other than interfacial energy relationships and their dependence on alloying and orientation.

# Rate of Evaporation of Zinc at Low Pressures

by H. W. St. Clair and M. J. Spendlove

**An automatic surface-follower mechanism was used to measure the surface temperature and the rate of evaporation of molten zinc while undergoing distillation at low pressure. At pressures of 50 to 100 microns Hg, the rate of evaporation may be 60 to 80 pct of the theoretical maximum corresponding to the measured temperature. The rate decreases rapidly at pressures above 100 microns Hg, to only 7 pct of the theoretical maximum at 2000 microns Hg. Measured temperature gradients at the surface are in agreement with theoretical gradients calculated from the heat of vaporization, rate of evaporation, and thermal conductivity of molten zinc.**

**T**HIS paper covers a series of careful measurements of the rate of evaporation of molten zinc at low pressures, undertaken as a part of a general investigation on the separation of metals by distillation.<sup>1</sup> Preliminary results on the rate of evaporation of zinc were described in a previous publication.<sup>2</sup> The results of the preliminary study are as follows:

1—The observed rates of evaporation of zinc were as high as 0.60 g per sq cm per min, corresponding to 75 pct of the maximum rate as determined by the temperature of the metal.

2—The evaporation rate was decreased from 0.30 g per sq cm per min at a pressure of 25 microns to only 0.09 g per sq cm per min when the pressure was increased to 5 mm.

3—The temperature of the surface during rapid evaporation may be 35° to 100°C less than the main mass of metal. Observed temperature gradients at the surface are consistent with those calculated from the heat of vaporization and the thermal conductivity of liquid zinc.

In the preliminary experiments, the rate of evaporation was determined from the loss in weight of the metal in the crucible during the test. This was compared with the weight of the condensate. Obviously, this method was subject to error because of some

uncertainty as to the period of evaporation that should correspond to the loss in weight. Furthermore, this method did not permit taking into account probable variations in the rate of evaporation during the test. A more serious shortcoming was that the temperature at the evaporating surface was not known, so the maximum theoretical rate of evaporation could not be calculated accurately.

To improve the precision of rate measurements and to allow accurate measurements of the surface temperature, a refined experimental technique was developed whereby the temperature and position of the surface could be measured accurately. This was done by an automatic surface-follower mechanism that gave a continuous record of the surface temperature and the amount of zinc evaporated. These data permitted an instantaneous determination of the actual rate of evaporation and the surface temperature throughout the test. Pure zinc (99.99 pct Zn) was used in all experiments.

## Description of Distillation Furnace

The details of construction of the distillation furnace are shown in Fig. 1. The furnace is enclosed in a large quartz tube open at one end. The open end of the quartz tube is sealed by means of a water-cooled head. The entire enclosure is vacuum tight. The connection between the water-cooled head and the quartz tube is sealed by means of a rubber gasket which fits tightly against the smooth end of the tube. The metal is heated by induced current set up in the molten zinc and the walls of the graphite crucible by means of a water-cooled induction coil outside the quartz tube. High frequency current is passed through the induction coil from a 6 kw mer-

Papers by authors of the U. S. Bureau of Mines staff are not subject to copyright.

cury-spark-gap frequency converter. The enclosure is evacuated by means of a rotary vacuum pump connected to the water-cooled head by a 2 in. pipeline. The condenser projects inside the quartz tube and is supported above the crucible by two cooling-water tubes that connect the condenser cooling coil to the condenser flange. The condenser insert sleeve extends from the condenser into the annular groove in the top of the crucible wall to prevent the escape of zinc vapor from between the crucible and the condenser. The flange on the condenser assembly fits tightly against the flange section at the upper end of the head. Coupling between the two flanges is likewise sealed by a rubber gasket. The atmospheric pressure acting against the flanges is sufficient to insure a vacuum-tight system.

The temperature of the main mass of metal in the crucible is measured by a thermocouple that projects up through the rubber stopper at the bottom of the quartz tube into a thermocouple well in a re-entrant dome at the bottom of the graphite crucible. Thermocouple wires in the base of the crucible are electrically shielded by the graphite crucible and the metal it contains. The surface-follower thermocouple wires are shielded by the water-cooled condenser. The absence of induction heating in the thermocouple wires was verified by measuring the melting point of zinc with power on the induction furnace and then observing the same temperature for the freezing point with the power turned off.

Pressure within the enclosure is measured by an ionization vacuum gage. A McLeod gage is used to verify all pressure-reading instruments at frequent intervals.

The zinc vapors evaporating from the surface of the molten metal rise to the water-cooled condenser, where they are collected on the cylindrical iron insert sleeves, which are removed from the condenser when the condensate is to be stripped.

### Operation of the Follower Unit

To measure the surface temperature of the metal during the course of an evaporation experiment, a special surface-follower mechanism was designed. It is schematically illustrated in Fig. 2. The surface-follower mechanism is mounted on a base plate that fits against the water-cooled condensing head (6) shown in Fig. 1. The surface-follower electrode (16) is supported by a movable carriage (7). The carriage is raised and lowered by means of a pair of vertical screws driven by a dc motor through a reduction gear. The motor runs continuously and is coupled to the carriage mechanism by means of a magnetic clutch (3). The clutch is energized through a set of contacts on a low-voltage relay. At the instant the follower electrode touches the metal surface, the relay circuit is closed and contacts for the magnetic clutch are opened. The de-energized clutch then slips, and the downward motion of the carriage stops, leaving the electrode and the thermocouple exactly at the metal surface. The downward motion starts again when the surface of the metal is lowered sufficiently by evaporation so that electrical contact with the surface-follower electrode is broken. This mechanism permits the follower electrode to indicate the rate of evaporation of the metal very accurately. During an evaporation test, the magnetic clutch engages and disengages with great rapidity.

A thermocouple for measuring the surface temperature is mounted on the same carriage as the surface-follower electrode. The position of this

Fig. 1—Vacuum distillation unit.

thermocouple is adjusted carefully at the beginning of the test by means of the thumb screw (9). The wall thickness of the protection tube is made very thin at the closed end where the thermocouple junction is located. The temperature indicated by the thermocouple is quite sensitive to the relative position of the thermocouple tube. The indicated temperature increases as the thermocouple is immersed below the surface and decreases above the surface, but there is a marked discontinuity in the temperature gradient at the surface. This discontinuity serves to indicate the proper position for the thermocouple to give an accurate indication of the surface temperature. It was found that the tube was in

Fig. 2—Surface-follower unit.

Fig. 3—Typical distillation test.

proper position when the tip of the protection tube projected approximately 1 mm into the liquid metal. Preliminary sensitivity tests revealed that the probable maximum departure from this position is 0.019 cm. The thermocouple response to such a variation in depth of immersion is negligible.

Movement of the carriage is permitted by sylphon bellows soldered to the carriage and base plate. Another smaller bellows is provided for the thermocouple support. The thumb screw and small bellows permit movement of the surface thermocouple to determine the variation of temperature above and below the evaporating surface during a test.

The position of the follower electrode is indicated by a counter attached to the shaft of the screw mechanism. The position is also recorded automatically by means of a sliding contact (24) upon the carriage, which picks up a voltage from the potentiometer (23). A constant low voltage is applied to the ends of the wire (22). The potential of the sliding contact is linearly related to the distance the carriage is above the zero position. This voltage is recorded on the strip-chart potentiometer and is easily calibrated to read in terms of weight of metal evaporated. The slope of the voltage-time curve is therefore proportional to the rate of evaporation. More accurate determination of the surface displacement is obtained by the revolution counter on the main drive shaft. The automatic surface follower thereby provides a means for simultaneously determining the surface temperature and the rate of evaporation at any time during the test.

A complete description of the mechanical and electrical characteristics is beyond the scope of this paper, but a detailed discussion of these is presented elsewhere.<sup>3</sup>

### Experimental Procedure

The general procedure followed in most of the evaporation tests was to evacuate the system to a pressure of the order of 25 microns and then raise the metal temperature to start evaporation. Evaporation begins shortly after the temperature exceeds the melting point. The follower electrode was lowered to the metal surface after the metal was completely melted but before appreciable evaporation had occurred. It was necessary to keep the electrode above the surface until after the metal was melted to avoid breaking the electrode tip on the solid metal when the electrode made contact.

In some experiments the metal was heated before evacuation. Evaporation was started by suddenly reducing the pressure in the system. In this way it

Fig. 4—Typical test on the distillation of zinc at different rates of evaporation.

was possible to obtain better control over the exact time at which evaporation started, but precautions had to be taken because of the sudden release of absorbed gas. The rapid evolution of the gas from the metal sometimes caused droplets of the metal to become entrained in the out-rushing gas and thereby were carried to the condenser by mechanical means rather than by true evaporation. Although the metal surface could not be observed visually in these experiments, the condition was determined by supplemental tests. A window section was put in the place of the follower unit and the metal surface was visually observed throughout the distillation period. Details of these observations are reported in another paper.<sup>2</sup> Early in the evaporating period a heavy film of fine material collects over most of the surface and then gradually disappears as the system comes up to temperature. The surface remains clean for the remainder of the test. Only slight turbulence of the zinc bath could be noted. The same conditions are assumed for experiments with the automatic surface follower.

### Results of Distillation Experiments

The results of a typical distillation test are shown in Fig. 3, in which the weight of metal evaporated, the crucible temperature, and the temperature of the surface of the metal are represented graphically against the duration of the test. It will be observed that there is a fairly constant rate of evaporation even at the beginning of the test when the temperature has not quite risen to maximum. The crucible temperature rises sharply to about 500°C, after which it levels off and becomes fairly constant. The surface temperature is about 15° to 20° lower than the crucible temperature.

During this test, the loss in weight of the crucible amounted to 1542 g, as compared to 1523 g, the weight of the condensate collected in the condenser. The weight of zinc indicated by the counter on the surface-follower mechanism was 1544 g, which agreed very well with the loss in weight of the crucible. The average rate of evaporation for the entire test per unit area of surface of the metal exposed to low pressure amounted to 0.384 g per sq cm per min. These data are typical. The weight of zinc evaporated as indicated by the counter usually approximates very accurately the loss in weight of the crucible. Weight of the condensate is usually about 10 to 20 g less than the weight of metal evaporated. This small amount of zinc vapor is lost by diffusion to other parts of the evacuated enclosure.

In test 24, Fig. 4, evaporation was started at a

power input of 3 kw. During this time the rate of evaporation was fairly constant, even though the crucible temperature was rising at the beginning and near the end of this part of the test. After about 70 min, power was increased to 4 kw. Shortly afterward, the rate of evaporation increased rather abruptly. The crucible temperature likewise increased and leveled off at 540°C. After 30 min, the power was increased further to 5 kw, and again the rate of evaporation increased proportionally. Tests shown in Figs. 3 and 4 were made at a pressure of 15 to 20 microns.

The interesting fact brought out by this experiment is that the rate of evaporation is more definitely related to the power input than to the crucible temperature or the surface temperature as recorded by the thermocouple on the surface follower. The surface temperature, as shown in this experiment, is abnormally low throughout most of the test, and it is likely that it does not represent the average surface temperature.

### Theory of Rate of Evaporation

The principal advantage of evaporation at reduced pressure is that high rates of evaporation are attained at relatively low temperatures. Evaporation at atmospheric pressure is retarded because the preponderance of gas molecules above the evaporating metal greatly impedes the diffusion of vapor molecules away from the surface. Under equilibrium conditions, such as exist when vapor-pressure measurements are made, the rate of evaporation from the molten metal is equal to the rate of condensation back onto the evaporating surface. The following expression has been derived from the effusion formula to express the theoretical maximum rate of evaporation into a perfect vacuum:<sup>2</sup>

$$W_o = p_o \alpha \sqrt{\frac{M}{2RT}} \quad [1]$$

where  $M$  is the molecular weight;  $R$ , the gas constant;  $p_o$ , the vapor pressure at temperature  $T$ ; and  $\alpha$ , the coefficient of condensation. As the value of  $\alpha$  is virtually unity for metals, the maximum rate of evaporation of zinc can be given by:

$$W_o = \frac{28.30 p_o}{T^{1/2}} \quad [2]$$

in which  $W_o$  is expressed in g per sq cm per min. This equation has been used to calculate the maximum rate of evaporation as given in this paper.

At very low pressures, the vapor molecules themselves offer the only impediment to the diffusion of vapor away from the surface. Their presence above the evaporating surface causes many molecular collisions, which cause some condensation back onto the surface. There is, however, a net rate of evaporation and recondensation. If, under these conditions, the partial pressure of the zinc vapor is  $p$ , the net rate of evaporation will be:

$$W = W_o \frac{28.30 p}{T^{1/2}} \quad [3]$$

which, combined with eq 2, gives:

$$W = \frac{28.30}{T^{1/2}} (p_o - p) \quad [4]$$

\* Vapor pressure of zinc for this calculation from U. S. Bureau of Mines, Bull. 383, p. 109.

As the observed rate of evaporation is  $W$  at a temperature for which the maximum rate of evaporation is  $W_o$ , it may be concluded that the zinc vapor is partly saturated. The degree of saturation represented by  $p/p_o$  is equal to:

$$p/p_o = 1 - W/W_o \quad [5]$$

### Variation of Evaporation Rate with Residual Gas Pressure

The rate of evaporation was measured for several tests in which the residual gas pressure was regulated at various assigned values while the power was held constant at 3.5 kw. The results of the tests are summarized in Table I. Variation of the observed rate of evaporation with respect to residual gas pressure is illustrated graphically by the solid line in Fig. 5. The rate of evaporation falls rapidly as the pressure is increased. A similar trend is shown by data obtained in previous experiments at lower rates of evaporation. These data are represented by the two dotted lines, representing evaporation at 1.9 and 1.2 kw, respectively.

The regulation of pressure at pressures of 100 microns or below was difficult because of the greater

Fig. 5—Rate of evaporation vs. residual gas pressure.

Fig. 6—Rate of evaporation in relation to continuously changing residual gas pressure.

time required for the vacuum pump to reduce the pressure, if it should momentarily be allowed to become too high. Therefore, no attempt was made to regulate the pressure below 100 microns. However, the rate of evaporation at 50 to 100 microns is of the order of 60 to 80 pct of the maximum rate, so that reducing the residual gas pressure below 100 microns will have much less effect than a corresponding decrease at higher pressures. It should be pointed out that the residual gas pressure as measured by the vacuum gage does not represent either the total gas pressure or the partial pressure of the residual gas at the evaporating surface. The partial pressure of the zinc may be many times the residual gas pressure. Furthermore, the partial pressure of the residual gas at the metal surface may be many times less than that in the condenser, because the evaporating zinc vapor sweeps the permanent gas molecules away. In other words, the evaporating zinc vapor has the same effect as mercury vapor in a diffusion pump.

At lower pressures there is greater freedom for effusion of vapors away from the molten metal surface, and the observed rate of evaporation becomes correspondingly nearer the calculated maximum rate as determined from the measured surface temperature. A comparison of the observed and maximum rate of evaporation is given in Table I under the heading  $W/W_0$ . In one instance the observed rate of evaporation is about 83 pct of the maximum at 100 microns. At 2000 microns it is about 7 pct of the maximum. The theoretical maximum rate of evaporation cannot be reached at high rates of evaporation even at extremely low pressures, because the greater concentration of vapor molecules above the surface

will partly obstruct the flow of other vapor molecules from the surface.

The effect of an increase in pressure of the residual gas in the system is to impede the diffusion of molecules of zinc vapor away from the surface, thereby increasing the partial pressure of zinc. The degree of saturation of the zinc vapor at the surface may be calculated from the observed rate of evaporation and the maximum rate corresponding to the surface temperature as shown in eq 5. The saturation as thus determined was as low as 17 pct at 100 microns pressure but increased to 96 pct at 2000 microns.

Two experiments were run in which the rate of evaporation was measured while the residual gas pressure was being continuously increased or decreased. In experiment 8, the pressure was gradually reduced at a uniform rate from 1000 to 100 microns. In experiment 9, the pressure was increased in the same manner at approximately the same rate from 50 to 1500 microns. These pressure adjustments were made by manually manipulating vacuum valves to throttle the vacuum pump. A careful record of the pressure measurements was kept throughout each test. Rates of evaporation corresponding to many different pressure measurements were calculated for each experiment. Two values for the rate of evaporation were thus obtained for each pressure. These data are represented graphically in Fig. 6.

In both experiments, an anomalous change in rate of evaporation occurs at pressures in the range of 300 to 400 microns. There is a sudden rise in the observed rate when the pressure decreases through this range, and the rate becomes more nearly constant when the pressure is increased through this range. No satisfactory explanation for this phenomenon has yet been determined.

The temperature decreased gradually from 489° to 447°C in test 8 and increased from 447° to 482°C in test 9. Temperature variations for the two tests are so nearly identical that curves are omitted for reasons of simplicity.

A series of tests was made to observe the rate of evaporation at several different power levels. These tests were continued for relatively long periods. The results are presented in Table II.

These data show that the total weight of the metal evaporated can be measured rather accurately by the surface-follower mechanism, the greatest error being about 2 pct in test 23. The relation between total power and the rate of evaporation is illustrated graphically in Fig. 7. It shows the total power required to evaporate at the observed rate. The curve is extrapolated to zero rate of evaporation and indicates that about 1.5 kw is needed to hold the system temperature at a point where evaporation starts. The power required for vaporization of zinc at the observed average rate of evaporation also is shown. The difference between the two curves represents the power losses.

It has been stated previously that starting evaporation by suddenly reducing the gas pressure above the molten metal is likely to result in an apparent rate of evaporation that is higher than the true rate would be. This is brought about by the rapid escape of absorbed gas, which carries droplets of metal from the molten surface into the condenser, where it solidifies as though it had actually been evaporated. Only five such tests were considered to give dependable rates of evaporation. Averages of the results for these five tests are as follows: The theoretical maximum rate of evaporation was 1.77 g per

Table II. Rate of Evaporation of Zn in Relation to Power

|        |                                |                  |                                      | 4.0       | 0.462                                        |
|        |                                |                  |                                      | 5.0       | 0.819                                        |

sq cm per min, and the observed rate was 0.577 g per sq cm per min, or 35 pct of the maximum. The average residual gas pressure was about 50 microns, and the zinc vapor near the surface was about 66 pct saturated.

### Temperature Gradient Near the Surface

The temperature of the metal at the surface, where evaporation is taking place, may be much cooler than the temperature of the main body of metal, as indicated by the crucible temperature. The difference between the crucible and surface temperatures is illustrated in Figs. 3 and 4. The difference is due to the cooling effect of rapid evaporation. The heat required to evaporate 1 g of zinc at 500°C is about 440 cal. The thermal conductivity of liquid zinc is 0.138 cal per sq cm per cm per sec per °C.<sup>4</sup> The temperature gradient required to evaporate  $W$  g of zinc per sq cm per min<sup>2</sup> is given by:

$$\frac{dt}{dx} = \frac{440 W}{60 \times 0.138} = 53W \quad [6]$$

This means that a temperature gradient of about 50°C per cm is required to evaporate zinc at a rate of 1 g per sq cm per min. The temperature distribution in the metal is determined by the flow of heat from the crucible walls and the adjacent metal where it is generated to the surface from which the metal is evaporated.

The surface-follower unit was used to measure the temperature gradient in the metal while evaporation was proceeding at a high rate. The follower automatically established the exact location of the surface as a reference while the thermocouple tube was manually adjusted. The results of this experiment are given in Fig. 8. The observed rate of evaporation as determined by the surface follower was 0.570 g per sq cm per min. The temperature

Fig. 7—Rate of evaporation vs. power.

Fig. 8—Temperature distribution near surface of evaporating zinc.

of the metal at the surface was 497°C, for which the thermal conductivity is 0.1381 (cal per sq cm per cm per sec per °C). The calculated temperature gradient necessary to evaporate zinc at the observed rate would therefore be 29.3°C per cm. It will be observed that this value is in very close agreement with the measured gradient.

Previous gradient measurements<sup>2</sup> were made at lower rates of evaporation. At a rate of 0.264 g per sq cm per min, the gradient was calculated to be 13.85°C per cm, and it too was in fairly good agreement with the observed temperature distribution.

### Summary and Conclusions

By means of an automatic surface-follower mechanism, careful measurements were made of the surface temperature and rate of evaporation of molten zinc while undergoing evaporation at a rapid rate at very low pressures. At pressures of 50 to 100 microns, the rate of evaporation may be 60 to 80 pct of the maximum theoretical rate. As the pressure of the residual gas increases above 100 microns, the rate decreases; at a pressure of 2000 microns the observed rate of evaporation was only 7 pct of the theoretical rate corresponding to the observed surface temperature.

The surface temperature during rapid evaporation is much lower than the average temperature of the metal because of the large amount of heat abstracted from the surface by the evaporating molecules. Measurements of the temperature gradient at the surface were in good agreement with the theoretical gradient calculated from the heat of vaporization, rate of evaporation, and thermal conductivity of molten zinc.

# Vapor Pressures of Zinc Over AgZn Alloys

by E. E. Underwood and B. L. Averbach

The vapor pressure of zinc in equilibrium with solid  $\beta$  AgZn alloys has been measured by the dew-point method. The thermodynamic activities of silver, and the molar heats of formation have been calculated. Similar measurements have been made for the ternary alloys formed by adding gold to AgZn. An apparent particle size effect has been observed for AgZn filings. The vapor pressure of zinc over filings is 15 to 20 pct higher than over the solid alloys.

STATISTICAL methods have been used to interpret the thermodynamic activities of the components of a solid solution in terms of average equilibrium atomic configurations. In some cases, the atomic arrangements can be measured by X-ray methods, and the results are usually expressed in terms of short range order parameters. Only in the cases of Cu<sub>3</sub>Au and AgAu have there been sufficient X-ray and thermodynamic data to verify the assumed correlation between the X-ray and the thermodynamic measurements. In Cu<sub>3</sub>Au the agreement is good; negative deviations from Raoult's law are observed and the number of Cu-Au nearest neighbor pairs predicted on the basis of the thermodynamic treatments agrees quite well with the number of such pairs observed by the X-ray methods.

The  $\beta$  brass alloys present a different set of conditions. The ordering is so rapid in these alloys that

the disordered state cannot be retained on quenching. In contrast, the disordered state in Cu<sub>3</sub>Au is easily retained on quenching. On heating, the ordered  $\beta$  brass loses its long range order continuously as the critical temperature is approached; in Cu<sub>3</sub>Au the order decreases slightly on heating and then drops discontinuously to zero at the critical temperature. These differences indicate that the short range order configurations in  $\beta$  brass systems may be of a different character than in Cu<sub>3</sub>Au systems. However, X-ray measurements of local order cannot be made in the Cu-Zn alloys because of the similarity in scattering factors. The alloy AgZn is isomorphous with CuZn, however, and recent experiments have indicated that there is a good possibility of observing short range order in this system.

Another complication arises in the case of  $\beta$  AgZn. The disordered body-centered cubic structure exists above 280°C. On quenching from above this temperature an ordered structure of the cesium-chloride type is formed. On slow cooling, however, a complex hexagonal structure, the  $\zeta$  phase, is produced; and if an ordered quenched alloy is reheated the  $\zeta$  phase begins to form above 80°C. It is thus difficult to study local order by X-ray methods in single crystals of AgZn since the  $\zeta$  phase formed on heating does not necessarily return to a single crystal of the original orientation. This problem has been met, however, by adding a few percent of gold to the AgZn. The gold suppresses the formation of the  $\zeta$

This paper represents a part of a thesis by E. E. Underwood submitted in partial fulfillment of the requirements for the degree of Master of Science to the Massachusetts Institute of Technology. This research program was sponsored in part by the Atomic Energy Commission under contract No. AT-30-1-GEN-368.

phase, without otherwise altering the structure, and this made it possible for Muldawer<sup>7</sup> to study the long range order in  $\beta$  AgZn as a function of temperature.

Local order measurements are being undertaken in the gold-bearing  $\beta$  AgZn alloys. In order to investigate the correlation between thermodynamic activities and short range order, the vapor pressures of zinc in equilibrium with various alloys of  $\beta$  AgZn and  $\beta$  AgZn plus Au were measured. These thermodynamic data are reported in this paper.

Several attempts have been made to detect the excess free energy associated with the formation of new surfaces. These experiments have, in general, been unsuccessful, and there has been no direct experimental verification of the Thompson equation which relates the practical size with the excess free energy. In this paper the vapor pressure of zinc in equilibrium with fine filings of  $\beta$  AgZn was meas-

Fig. 2—Temperature gradient along furnace tube.

calibrated against a Bureau of Standards Pt-Pt-10 pct Rh thermocouple, were used.

The alloys were prepared from silver shot, more than 99.99 pct pure, and from zinc sticks of about 99.98 pct Zn; for the ternary alloys, gold of 99.96 pct purity was added. Melts were made in a graphite crucible in an induction furnace, and the crucible and melt were quenched into water to minimize segregation. The ingot was machined to a  $\frac{3}{4}$  in. diam cylinder and annealed in an evacuated tube at 640°C for several days. The  $\frac{3}{8}$  in. diam specimen was then prepared, thoroughly degreased, and sealed into the clear quartz tube.

Each specimen was held at temperature overnight in the quartz tube and observations were started on the following morning by lowering the temperature at the opposite end of the furnace. After the first deposit of liquid zinc droplets was observed, the temperature of the droplets was raised until they evaporated, then lowered slowly until they reappeared. This process was repeated until the equilibrium temperature was determined. At the higher vapor pressures the dew point could be determined within  $\pm 1^\circ\text{C}$ , but at lower pressures only within  $\pm 2^\circ\text{C}$ . Chemical analyses of the specimens before and after the dew-point determinations agreed closely and indicated that a negligible amount of zinc had been lost during the measurements.

It is believed that dezincification of the alloy surfaces did not occur to any noticeable extent. The vapor pressure measurements were performed at relatively high temperatures where the diffusion

Fig. 1—Sketch of furnace cross-section.

ured and found to be measurably higher than the vapor pressure in equilibrium with a bulk sample of the same alloy. This excess vapor pressure was associated with the large local curvature present in the filings, although no experimental measurement of this local curvature was made.

### Experimental Method

The Hargreaves<sup>8</sup> dew-point method was used to measure the vapor pressure of zinc over solid alloys. In this method an alloy is placed at one end of an evacuated clear quartz tube which has a deep thermocouple well at each end and a side arm for evacuation and sealing. The sample was a  $\frac{3}{8}$  in. diam cylinder 1  $\frac{1}{16}$  in. long and contained a hole drilled into one end so that the sample could slip over the thermocouple well. The quartz tube was placed inside a tube furnace heated by three separately controlled resistance windings and so arranged that the end of the evacuated tube containing the alloy could be maintained at a constant temperature,  $T_h$ , while the temperature at the other end of the tube could be lowered to a selected temperature  $T_c$ . When  $T_c$  was below the dew point of the zinc vapor, droplets of liquid zinc were observed over the thermocouple well at the cold end, and the equilibrium value of  $T_c$  was taken as halfway between the closest temperatures of condensation and evaporation.

The furnace is shown schematically in Fig. 1 and a typical temperature gradient for this furnace is shown in Fig. 2. A small coil, independently controlled, was placed around the condensation end of the quartz tube for fine temperature control. The maximum fluctuation observed at the hot end of the tube was  $\pm 1^\circ\text{C}$ . Chromel-alumel thermocouples,

Fig. 3—Plot of  $\frac{1}{T_h}$  vs.  $\frac{1}{T_c}$  for binary alloys.

Fig. 4—Activities of silver and zinc in Ag-Zn alloys at 620°C. Activity of zinc referred to liquid zinc.

rates are quite large. In a closed system where no zinc is lost to the atmosphere, it would be expected that a steady state would be reached rather quickly and the specimen would attain a uniform composition.

The vapor pressure measurements were made on each sample at a series of temperatures. The experimental points shown in Fig. 3 were not taken in sequence and no systematic deviations of vapor pressure were noted during the long periods of time (10 to 14 days) during which the specimens were at temperature. Furthermore, the amount of zinc in the vapor phase is negligibly small. At the highest pressures encountered, about 0.001 g Zn would be in the vapor phase, while the weight of the sample was about 12 g.

In addition, check runs were made later with the same specimens, and the confirmation of the original data was quite satisfactory, see Fig. 3. Table I shows that the vapor pressures of zinc over the bulk alloys were the same, within experimental error, as those over the corresponding preheated powders. This would not be expected if dezincification had occurred. Finally, a comparison of the dew-point method for measuring vapor pressures over  $\alpha$  Cu-Zn alloys<sup>8</sup> with the absorption spectra method,<sup>9</sup> the weighing method,<sup>10</sup> and the carrier-gas method<sup>11</sup> shows the dew-point method to good advantage.

A one degree error in  $T_c$  was found to introduce a relative error of 2.5 pct in the activity of zinc. Deviations in chemical analyses averaged between 1 to 2 pct and the overall error was estimated at 5 to 10 pct.

### Experimental Results

The experimental values may be checked quickly for consistency by plotting  $\frac{1}{T_h}$  vs.  $\frac{1}{T_c}$ . If the vapor pressure throughout the tube is considered to be the

same, the Clausius-Clapeyron equation for each end may be written as:

$$\ln p = \frac{-\Delta H_v}{RT_h} + C = \frac{-\Delta H_v^\circ}{RT_c} + C' \quad [1]$$

where  $p$  is the zinc vapor pressure within the tube;  $\Delta H_v$  and  $\Delta H_v^\circ$  are the heats of vaporization of zinc from the alloy and from pure liquid zinc, respectively;  $R$ , the gas constant; and  $C$  and  $C'$ , the integration constants. If  $\Delta H_v$ ,  $\Delta H_v^\circ$ ,  $C$ , and  $C'$  are taken as independent of temperature:

$$\frac{1}{T_h} = K \cdot \frac{1}{T_c} + K' \quad [2]$$

Fig. 3 shows such a plot of the experimental temperatures with the best straight lines determined by the method of least squares. The vapor pressures for pure zinc were obtained from the equations of Kelley.<sup>3</sup> The activities and activity coefficients of zinc with respect to liquid zinc are listed in Table I. The activities of silver at three temperatures were calculated by means of the Gibbs-Duhem equation. The activities for zinc and silver at 620°C are shown in Fig. 4, and the activities of zinc are indicated on the Ag-Zn equilibrium diagram in Fig. 5.

Birchenall and Cheng<sup>4</sup> obtained only one point within the  $\beta$  field and this is somewhat lower than the corresponding value obtained in this investigation. However, the vapor pressure of one alloy in the  $\alpha$  region containing 31.3 atomic pct Zn was measured and showed good agreement with the Birchenall and Cheng data. These data, plus those of Schneider and Schmid<sup>5</sup> for liquid Ag-Zn alloys at 700°C, are shown in Fig. 6. The similarity to the data for solid alloys is quite striking. In order to compare the data for liquids with the data obtained in this research, the zinc activities for the solid alloys were extrapolated to the solidus at 700°C and compared with the corresponding value for the activity of the liquid in equilibrium with this composition. The activities (referred to liquid zinc) were 0.24 from the extrapolation of the solid values and 0.26 from the liquid data.

Partial molar heats of formation, relative to pure solid zinc or silver, were calculated for several com-

positions in the  $\beta$  field from the slopes of the straight lines obtained by plotting  $\ln a_{\text{Zn}}$  or  $\ln a_{\text{Ag}}$  vs.  $\frac{1}{T}$ . The relative integral molar heat of formation at the composition AgZn was approximately -1880 cal per mol and the corresponding partial molar heats were  $\Delta\bar{H}_{\text{Zn}} = -1590$  and  $\Delta\bar{H}_{\text{Ag}} = -2170$  cal per mol.

**Ternary Alloys:** The addition of 3 atomic pct Au to  $\beta$  AgZn alloys is sufficient to suppress the formation of the  $\zeta$  phase. The vapor pressure of zinc was measured for two alloys with 3.33 and 6.68 atomic pct Au and the data are summarized in Table I. The zinc vapor pressures of the two ternary alloys were less than those from corresponding binary

Ag-Zn alloys at the same temperature. Schneider and Schmid<sup>5</sup> showed that the activities of zinc in liquid Au-Zn alloys were lower than in Ag-Zn alloys. Hargreaves<sup>2</sup> measured the zinc vapor pressures over solid Ni-Cu-Zn alloys and also found a decrease in vapor pressure in comparison with the Cu-Zn alloys.

**Powdered Alloys:** Ag-Zn powders were prepared by filing from the same homogenized castings that were used to obtain specimens for the vapor pressure measurements. Clean files and a decreased vise were used, and iron fragments were removed with a permanent magnet. Only particles which would pass a 325 mesh screen were used. The powder was fed into one end of the cleaned quartz tube up to the point usually occupied by the solid specimens and packed as much as possible by tapping. After heating the as-filed particles, a light brown cloudy film appeared at the cold end of the tube but the liquid droplets could still be observed. Vapor pressure measurements were also made on filings which had been preheated at 560°C for two days. In these cases the brown film was not observed.

A significant increase in the vapor pressure was obtained over the as-filed powders in comparison with the bulk material. These differences have been summarized in Table II. The ratio of the zinc vapor

pressure over the filings,  $p'$ , to the pressure over the bulk alloys,  $p$ , is approximately 1.15 to 1.20.

According to the Thompson equation:

$$\ln \frac{p'}{p} = \frac{2\sigma \bar{V}}{RT\bar{r}}$$

where  $\sigma$  is the specific surface free energy;  $\bar{V}$ , the partial molar volume;  $R$ , the gas constant;  $T$ , the temperature; and  $\bar{r}$ , the effective radius of curvature. Assuming a value of 700 ergs per sq cm for  $\sigma$  at 800°K, the effective radius of curvature,  $\bar{r}$ , is calculated to be approximately 0.03 microns.

This effect can be explained in terms of the shapes of typical filings observed under the microscope. The filings contain many sharp, jagged edges and the net effect of such peaks could produce this increase in vapor pressure, provided that the effective radius of curvature was small enough and that the radius of curvature of the valleys was much larger. The valleys need not necessarily cancel the increase in pressure due to the peaks, unless the valleys had much the same (negative) radius of curvature. The sharp edges of the as-filed powders were found to be somewhat rounded off after the runs had been completed. However, it can be said that when sharp-edged particles were introduced into the furnace, higher vapor pressures resulted than when rounded particles were used initially.

The zinc vapor pressures of the filings preheated

Fig. 6—Activity of zinc in Ag-Zn alloys, referred to liquid zinc.

Fig. 7—Cross-sections of Ag-Zn filings.

for two days at 560°C were determined next. The activities of zinc for the preheated powders are essentially the same as those obtained for the corresponding bulk alloys and the values are listed in Table I. A metallographic examination of these preheated powders showed that the jagged edges had been rounded off approximately as shown in Fig. 7.

Neither powder showed any appreciable evidence of sintering as a result of the heating incidental to the vapor pressure measurements. Chemical analyses of the filings after the runs checked closely with the original analyses.

### Discussion of Results

A correlation between the measured activity coefficients and the corresponding equilibrium atomic arrangement can only be made in an approximate fashion. As a starting point it may be assumed that the entropy of mixing for zinc and silver atoms in the body-centered cubic solution is ideal and the heat of mixing may be interpreted in terms of nearest neighbor interactions. For a regular solution it can be shown<sup>8</sup> that:

$$\frac{ZN_{\nu}(1 - X_A)^2}{RT} = \ln \gamma_A \quad [4]$$

where  $Z$  is the number of nearest neighbors,  $N_{\nu}$ , Avogadro's number;  $X_A$ , the atomic fraction of component A;  $\gamma_A$ , the activity coefficient of component A; and  $\nu = E_{AB} - \frac{1}{2}(E_{AA} + E_{BB})$ , the interaction energy. This equation only applies to the case where the activity coefficients are referred to a pure metal A which has the same crystal structure as the alloy. However, in the  $\beta$  AgZn region, the activities of the zinc in the body-centered cubic alloy have been referred to the pure solid metal in the hexagonal close-packed form. A straightforward calculation of the interaction energy from the measured activity coefficients thus contains a structural contribution from the hypothetical phase change Zn(hexagonal close-packed) = Zn(body-centered cubic).

The activities for the 50.3 atomic pct Zn alloy were calculated with respect to solid zinc as a standard state and these values were used to evaluate  $\nu$ . On

plotting  $\ln \gamma_{zn}$  as a function of  $\frac{1}{T}$  a straight line was

obtained and the slope of this line gave a value of -790 cal per mol for  $N_{\nu}$ . Cowley<sup>7</sup> has derived an approximate relationship for  $\beta$  brass structures between the interaction energy  $\nu$  and  $T_c$ , the critical temperature for long range order:

$$\frac{N_{\nu}}{R} = \frac{-T_c}{4} \quad [5]$$

Recently the long range order was measured by Muldawer<sup>1</sup> in several ternary AgZn plus Au alloys. On extrapolating the critical temperatures to binary AgZn, a value of 270°C was obtained for  $T_c$ . This corresponds to -275 cal for  $N_{\nu}$ . The difference, -515 cal per mol, may be assigned to the hypothetical phase change Zn(hexagonal close-packed) = Zn(body-centered cubic). This value, however, cannot be verified experimentally.

It is difficult to reconcile the apparent higher vapor pressures observed over the filings in terms of a particle size effect alone. The 15 to 20 pct increase in vapor pressure corresponds to a local curvature of 0.03 microns, but the classical Thompson equation may not be valid for particles with such small radii of curvature. It is quite possible that surface contamination or the greatly disturbed surface due to the filing operation also contributed to the effect on vapor pressure.

### Summary

The thermodynamic activities in three solid  $\beta$  Ag-Zn alloys have been obtained over a temperature range of 500° to 660°C. The activities of silver and the molar heats of formation have been computed. Similar measurements have also been made for ternary AgZn-plus Au alloys.

An apparent particle size effect has been observed in the case of AgZn filings. The vapor pressures of zinc over -325 mesh filings were 15 to 20 pct higher than over solid alloys.

# Analytical Representation of Certain Phase Boundaries

by W. Rostoker

Using an expression for the free energy of a homogeneous phase as a function of composition, a relationship is derived which interrelates the phase boundaries extending from the allotropic transformation of the solvent metal. Comparisons between observed and calculated phase boundaries in the systems Fe-Ni, Fe-Mn, Fe-W, Ti-Mo, and Ti-Cb are presented.

IT is the purpose of this paper to illustrate how the general free energy equations for two phases in equilibrium may be used to derive an expression which interrelates the phase boundaries extending from the allotropic transformation of the solvent metal. The free energy per gram atom of a disordered solid solution may, for many purposes, be represented by the equation:<sup>1</sup>

$$F = \frac{1}{2}NZ [C \cdot V_{AA} + (1-C) V_{BB} + 2C(1-C)V] + K(T) + RT [C \cdot \ln C + (1-C) \ln(1-C)] \quad [1]$$

where  $N$  is Avogadro's number;  $Z$ , the coordination number;  $C$ , the concentration of the solute element in atomic percent; the subscripts refer to concentrations at phase mixture boundaries;  $V_{AA}$ ,  $V_{BB}$ , and  $V_{AB}$  are the bond energies between like and unlike adjacent atoms, respectively, at the interatomic spacing characteristic of the phase. The bond energies are usually assumed to be independent of small changes in the lattice parameter occasioned by solute additions and variations in temperature;  $V = V_{AB}$

$$- \frac{V_{AA} + V_{BB}}{2}; K(T) \text{ is the sum of the heat con-}$$

tent and heat entropy;  $R$ , the molar gas constant; and  $T$ , the temperature in degrees Kelvin.

The free energy of a homogeneous phase is there-

W. ROSTOKER is associated with the Metals Research Dept., Armour Research Foundation and is Assistant Professor of Metallurgical Engineering, Illinois Institute of Technology, Chicago.

fore the sum of an internal energy, a specific heat, and a configurational entropy term, respectively. The compositions of two phases in equilibrium at a given temperature are governed by the minimum total free energy principle. Graphically, this is represented by the points of tangency of the tangent common to the free energy vs. concentration curves of the two phases.

Analytically, this may be expressed as:

$$\left( \frac{dF}{dc} \right)_\alpha = \left( \frac{dF}{dc} \right)_\beta \quad [2]$$

Expanding both sides using eq 1, the following equation is obtained after convenient readjustment of the terms:

$$RT \ln \left[ \left( \frac{C_\beta}{1-C_\beta} \right) \left( \frac{1-C_\alpha}{C_\alpha} \right) \right] = \frac{1}{2}N \frac{(V_{AA} - V_{BB})(Z_\alpha - Z_\beta) + NV}{[Z_\alpha(1-2C_\alpha) - Z_\beta(1-2C_\beta)]} \quad [3]$$

The following assumptions have been made at this point:

1—The specific heats of the two phases are independent of composition variations within the range under consideration. Accordingly, the  $K(T)$  terms disappear on differentiation.

$$2—(V_{AA})_\alpha = (V_{AA})_\beta; (V_{BB})_\alpha = (V_{BB})_\beta; V_\alpha = V_\beta$$

The justification for these assumptions can lie only in the successful application of the resultant equation. It may be noted that Zener<sup>2</sup> has used assumption 1 in the calculation of the boundaries limiting the  $(\alpha+\beta)$  phase mixture in the Cu-Zn system.

Fig. 1—Calculated, dashed line, and observed,<sup>8</sup> solid line, boundaries in the Fe-Ni system.

Fig. 2—Calculated, dashed line, and observed,<sup>6</sup> solid line, boundaries in the Fe-Mn system.

Fig. 3—Calculated, dashed line, and observed,<sup>8</sup> solid line, boundaries in the Ti-Mo system.

Eq 3 may be reduced to a more simplified form:

$$RT \ln \left[ \left( \frac{C_\beta}{1-C_\beta} \right) \left( \frac{1-C_\alpha}{C_\alpha} \right) \right] = K_1 [Z_\alpha - Z_\beta] + K_2 [Z_\alpha(1-2C_\alpha) - Z_\beta(1-2C_\beta)] \quad [4]$$

where  $K_1 = \frac{1}{2}N(V_{AA} - V_{BB})$  and  $K_2 = NV$ . The values of the constants may be calculated from reliable data for  $C_\alpha$ ,  $C_\beta$  at two temperatures. Eq 4 has been applied to several cases of phase mixture boundaries extending from the allotropic transformations of pure iron. Recent work on certain titanium-rich systems has permitted additional interesting examinations of the above relationship.

In the Fe-Ni system, the composition of the rejected  $\alpha$  phase is isothermally invariant with time and consequently the accurate experimental location of the  $\alpha/(\alpha+\gamma)$  boundary is much less difficult than the corresponding  $(\alpha+\gamma)/\gamma$  boundary of the phase mixture. Using the data for the  $\alpha/(\alpha+\gamma)$  boundary and two reliable values of  $C_\gamma(T)$ , the whole  $(\alpha+\gamma)/\gamma$  boundary may be calculated by successive graphical solutions of eq 4.

The calculation for the Fe-Ni system may be summarized as follows: Using data from Owen and

Sully,<sup>8</sup> constants  $K_1$  and  $K_2$  were evaluated as  $K_1 = 703$  and  $K_2 = 140$ . Eq 4 becomes (since  $Z_\alpha = 8$  and  $Z_\gamma = 12$ ):

$$RT \ln \left[ \left( \frac{C_\gamma}{1-C_\gamma} \right) \left( \frac{1-C_\alpha}{C_\alpha} \right) \right] = 2248 + 1128 \frac{[3C_\gamma - 2C_\alpha]}{[3C_\gamma - 2C_\alpha]}$$

The value of  $C_\gamma$  corresponding to a given  $C_\alpha$  may be found from the intersection of curves of:

$$RT \ln \left[ \left( \frac{C_\gamma}{1-C_\gamma} \right) \left( \frac{1-C_\alpha}{C_\alpha} \right) \right] \text{ vs. } C_\gamma$$

$$2248 + 1128 [3C_\gamma - 2C_\alpha] \text{ vs. } C_\gamma$$

Fig. 1 shows a good agreement between calculated and experimental boundaries.

Similar calculations have been applied to the same type of phase boundaries found in the systems Fe-Mn, Ti-Mo, and Ti-Cb. The results are graphically represented in Figs. 2, 3, and 4, respectively. Fig. 5 shows that the same treatment may be applied to the closed  $\gamma$  loop of the Fe-W system. The constants for the equations are summarized in Table I. It will be seen that the assumptions regarding the independence from composition of certain free

Fig. 4—Calculated, dashed line, adjusted, dash-dot line, and observed,<sup>8</sup> solid line, boundaries in the Ti-Cb system.

Fig. 5—Calculated, dashed line, and observed,<sup>7</sup> solid line, boundaries in the Fe-W system.

energy terms is valid in several cases for solute concentrations of as much as 30 atomic pct.

A useful application of this analytical method arose in the study of the phase boundaries for the titanium-rich Ti-Cb system. The  $\alpha/(\alpha+\beta)$  boundary was first drawn as the best fit between brackets established by micrographic analysis at various temperatures. Using points from this boundary to calculate the  $(\alpha+\beta)/\beta$  boundary yielded results widely divergent from the experimental work. By trial and error, it was found that a reasonable corroboration could be obtained if the  $\alpha/(\alpha+\beta)$  boundary was redrawn in a new position which also lay within the confines of the brackets imposed by the data. It is suggested that eq 4 may be applied to experimental phase boundaries as a check of self-consistency.

It will be noted that the constant  $K_1$  is represented as the difference between two terms which embody the molar cohesive energies of the pure components divided each by the coordination number. Using published data for molar cohesive energies<sup>4</sup> and the coordination number of the high temperature allotropic modification, calculated values for  $K_1$  are presented in Table I for comparison with the observed values. For example, the calculation of  $K_1$  for the Fe-Ni system proceeds as follows:

$$K_1 = \frac{1}{2} N (V_{\text{Fe-Fe}} - V_{\text{Ni-Ni}}) =$$

$$\left[ \frac{\text{molar cohesive energy of Fe}}{12} - \frac{\text{molar cohesive energy of Ni}}{12} \right]$$

$$= \left[ \frac{94000}{12} - \frac{85000}{12} \right]$$

$$= 750 \text{ cal}$$

The agreement in general is quite good, considering that no temperature corrections were made and that the published data pertains to cohesive energies at

Table I. Summary of Constants

| System | $K_1$   | $K_2$ | $K_1$ (As Calculated from Eq 4) |
|--------|---------|-------|---------------------------------|
| Fe-Ni  | +703    | +140  | +750                            |
| Fe-Mn  | +1535   | +257  | +1670                           |
| Fe-W   | -16,250 | -9500 | -18,410                         |
| Ti-Mo  | +5085   | -448  | +7500                           |
| Ti-Cb  | -4050   | +2700 | -4000                           |

Fig. 6—Hypothetical free energy vs. concentration curves illustrating a possible origin of the indeterminate location of a phase boundary.

the interatomic spacings of the pure metals, rather than their acquired spacings in solid solution.

The calculated  $(\alpha+\gamma)/\gamma$  boundary of the Fe-Ni system tends towards parallelism with the abscissa in the composition range which has always been the most difficult to study. The same effect may be noted in the cases of the Fe-Mn, Ti-Mo, and Ti-Cb systems (see Figs. 2, 3, and 4). This trend could be due to a breakdown of the assumptions upon which eq 4 are founded. On the other hand, the same effect could arise if the free energy vs. composition curve for the  $\gamma$  or  $\beta$  phase became approximately linear such that no unique tangent could be drawn. This is diagrammatically shown in Fig. 6. An examination of free energy data obtained by Kubaschewski and v. Goldbeck<sup>5</sup> indicate that this condition is possible.

There seems to be sufficient evidence that phase boundaries of the types considered can be represented by an equation derived from fundamental free energy relationships but involving certain ad hoc assumptions. An attempt to treat the  $(\alpha+\beta)$  boundaries of the Cu-Zn system by the same method met with no success. This mention should serve to emphasize that eq 4 has limited application.

A much more elaborate development of this subject along classical thermodynamic lines has been published by Zener.<sup>9</sup> The writer feels justified in presenting this alternative treatment because of its greater simplicity and because the results, while not as widely applied, are at least as closely in agreement with experimental data.

### Acknowledgment

This work was associated with a contract (Contract No. AF 33 (038)-8708, E.O. No. 605-225) to the Armour Research Foundation from the Materials Laboratory, Engineering Division, Air Materiel Command, and is published with their permission. The writer wishes to express his appreciation to M. Hansen for stimulating discussions.

# Surface Tension of Solid Silver

by E. R. Funk, H. Udin, and J. Wulff

The surface tension of solid silver is measured by a refinement of the Udin, Shaler, and Wulff technique. The tests were made in a purified helium atmosphere at four different temperatures and various times. The average of the results is  $\gamma = 1140 \pm 90$  dynes per cm for the range  $875^\circ$  to  $932^\circ\text{C}$ .

A SUCCESSFUL measurement of the surface tension of solid copper was reported by Udin, Shaler, and Wulff.<sup>1</sup> They performed experiments on copper held in vacuum within  $100^\circ\text{C}$  of the melting point. At these temperatures, the creep rate in 5 and 3 mil copper wires was sufficient to permit determination of a balance between the contractile force

E. R. FUNK, Junior Member AIME, H. UDIN and J. WULFF, Members AIME, are Instructor, Assistant Professor, and Professor of Metallurgy, respectively, Massachusetts Institute of Technology, Cambridge, Mass.

Discussion on this paper, TP 3188E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, July 11, 1951. New York Meeting, February 1952.

of surface tension and the extending force of small copper weights joined to the end of the wire specimens. By suspending a series of variously weighted specimens and measuring the change in a gage length during the test, the balancing applied load could be found. This point of zero strain is a measure of the surface tension. The mathematical formulation of this gives:

$$w = \pi r \gamma \quad [1]$$

where  $w$  is the weight for zero strain;  $r$ , the radius of the wire; and  $\gamma$ , the surface tension.

A subsequent note by Udin<sup>2</sup> pointed out that eq 1 applies only to single-crystal specimens. Since the specimens used revealed a "bamboo" structure upon

\* Specimens numbered according to the position occupied in the cell cover.

metallographic examination, the equation must be modified to take into account the grain boundary energy. Since the grain boundaries are perpendicular to the axis of the wire, eq 1 becomes:

$$w = \pi r \gamma - \left(\frac{n}{l}\right) \pi r^2 \gamma_{gb}$$
 [2]

where  $\gamma_{gb}$  is the interfacial tension of a grain boundary and  $n/l$ , the number of grains per unit length.

Greenough<sup>3</sup> has shown, and further experiments in this laboratory have confirmed, that for silver in an inert atmosphere, the grain boundary interfacial tension for the average grain boundary is one third the tension of the free surface. Therefore eq 2 may be rewritten as:

$$w = \pi r \gamma \left[1 - \frac{n}{l} \frac{r}{3}\right]$$
 [3]

For the special case of the wires in our experiments  $n/l$  is  $60 \pm 10$  grains per cm and  $r$  is 0.0065 cm, so that the equation relating the surface tension to the balancing load for polycrystalline wires is then:

$$w = \pi r \gamma [0.87]$$
 [4]

The applied stress for zero strain is the balancing load divided by the cross-sectional area of the wire:

$$\gamma = \frac{\sigma_{\epsilon=0} r}{0.87}$$
 [5]

where  $\sigma_{\epsilon=0}$  is the applied stress for zero strain.

Experimental Procedure

The techniques used by Udin, Shaler, and Wulff were used in modified form to measure the surface tension of solid silver. The wire was 0.00508 in. in diam and was drawn from a billet of high purity, vacuum cast silver. Preliminary experiments showed that commercially available fine silver wire was not suitable for this work because uninhibited grain growth did not occur, presumably due to the presence of oxides or other inclusions.

Two gage marks were cut into the wire approximately 1 cm apart so that the strain in the specimens could be measured. These marks were made by rotating the wire against the edges of spaced razor blades in an especially designed machine.<sup>4</sup> Each end weight, prepared from a length of the silver wire, was melted on a charcoal block and the end of the wire thrust into the molten ball as it solidified. In all the runs, 10 to 13 wires were used with external end weights ranging from 0 to 120 mg.

The wires were suspended from a silver cell cover

Fig. 1—Silver cell with thermocouple well.

and then the array was carefully transferred to a silver cell. The cover closed but did not seal the cell. The cell, shown in Fig. 1, was then transferred to a platinum wound Inconel tube furnace. This furnace has been described elsewhere.<sup>1</sup>

Preliminary runs were carried out in a vacuum of  $5 \times 10^{-6}$  mm Hg, but the evaporation of the silver wires at the test temperatures was so rapid that no reproducible results could be obtained. The runs reported here were therefore carried out in a purified helium atmosphere. A helium flow of 3 cu cm per sec was maintained in the furnace throughout the run. The helium was purified by passing it through an activated charcoal trap held at liquid nitrogen temperatures.

Due to the manipulation required for mounting, the wires were often slightly bent and cold worked. An anneal treatment of a few minutes at 600°C was sufficient to allow straightening of the wires.

The specimens were washed in alcohol and ether

Fig. 2—Temperature dependence of the surface tension of solid silver.

to remove dirt and returned to the furnace for a high temperature anneal. This anneal lasted 1 hr at 940°C. The specimens were removed from the furnace after cooling, and the gage length of each wire was measured with a vertical traveling microscope with a screw accurate to  $\pm 0.00015$  cm. This array was returned to the furnace for the run which lasted up to 116 hr for the lower temperatures and as short as 18 hr for the higher temperatures. Upon cooling the wires were removed from the furnace and the gage lengths again measured. The weights were clipped off at the weld and weighed to  $\pm 0.1$  mg.

It was always possible to count the number of grains in each wire after a test was completed. This is possible because an equilibrium of surface forces exists where the grain boundary meets the free surface. The groove angle established at the grain boundary<sup>3, 4</sup> is distinctly visible under diffuse oblique illumination at X50. These grooves are often visible even after the short 940°C anneal. A grain count on a number of specimens after the anneal and also after the test itself showed that the grain size established during the anneal remains essentially unchanged.

Table II. Summary of Experimental Results

| Test No. | Test Temperature, °C ( $\pm 1^\circ\text{C}$ ) | Duration of Test, Hr | Surface Tension, Dynes per Cm |
|----------|------------------------------------------------|----------------------|-------------------------------|
| 22       | 938                                            | 18                   | 1110                          |
| 23       | 941                                            | 29                   | 1150                          |
| 24       | 923                                            | 18                   | 1190                          |

| 26       | 923                                            | 36                   | 1115                          |
| 27       | 907                                            | 50                   | 1210                          |
| 28       | 907                                            | 108                  | 1215                          |
| 29       | Run lost                                       |                      |                               |
| 30       | 924                                            | 64.5                 | 1005                          |
| 31       | 876                                            | 116                  | 1045                          |
| 32       | 938                                            | 59.5                 | 1070                          |

The surface tension for all runs was calculated from eq 5. A straight line fits the data for applied stress between 0 and  $4 \times 10^5$  dynes per sq cm. Points of larger applied stress were not included in the calculation. A least square calculation was used to determine the most probable stress at zero strain. The necessary but small ( $0.15 \times 10^5$  dynes per sq cm) correction to the ball weight for the weight of the wires between the lower gage mark and the weight was also made.

The values for the applied stress and the resulting strain for each specimen in each successful run are given in Table I. A summary of the experimental results is presented in Table II.

## Discussion and Conclusions

Ten tests for the surface tension of solid silver in a purified helium atmosphere were made at four different temperatures and various times. The average of the results is  $\gamma = 1140 \pm 90$  dynes per cm for the range 875° to 932°C. There is a tendency for short time runs to give slightly higher values for surface tension than runs of long duration. This trend seems to occur at all the test temperatures but is, in general, less than the experimental error. If it is a real phenomena, it may be attributable to one of several reasons. There may be a gradual adsorption of traces of metallic vapor contaminant. More likely, the average diameter of the wires decreases due to evaporation. This decrease would not have been detected if it was less than  $5 \times 10^{-5}$  in., and such a decrease would lead to a decrease of some 20 to 40 dynes per cm in the apparent value of the surface tension.

Fig. 2 shows the temperature dependence of the surface tension. In spite of the scatter of the data, probably attributable in a large part to the high sensitivity of silver to gaseous contamination, a least square calculation of the ten tests gives a temperature coefficient of  $-0.47$  dynes per cm of °K. This is in good agreement with the coefficient theoretically predicted by the Eötvös rule. This rule says that the surface tension of a liquid decreases linearly to zero at the critical temperature. Assuming a critical temperature of 3330°K and, correcting for a liquid-solid interfacial tension of 200 dynes per cm,<sup>6, 7</sup> the Eötvös rule coefficient is  $-0.45$  dynes per cm per °K. It is assumed that Antonow's rule holds at the melting point so that the sum of the liquid-vapor surface tension and the liquid-solid surface tension equals the solid-vapor surface tension.

# Surface Tension of Solid Gold

by F. H. Buttner, H. Udin, and J. Wulff

Using a modified Udin, Shaler, and Wulff technique, the surface tension of gold in purified helium was found to be  $1400 \pm 65$  dynes per cm for the temperature range  $1017^\circ$  to  $1042^\circ\text{C}$ .

IN the original Udin, Shaler, and Wulff technique for measuring the surface tension of copper,<sup>1</sup> variably weighted wires were allowed to extend or contract in a copper cell held at elevated temperatures in vacuum. By plotting stress vs. strain for a wire array in one test, the stress at zero strain is obtained. This is the point where the contractile forces resulting from surface tension are balanced by the applied load, according to the expression:

$$\gamma = \sigma_{\epsilon=0} r \quad [1]$$

where  $\gamma$  is the surface tension in dynes per cm;  $\sigma_{\epsilon=0}$ , the stress at zero strain in dynes per cm; and  $r$ , the radius of the wire in cm. The assumption that the wires deform viscously permits the drawing of a straight line through the points on the stress-strain plot. Justification of the assumption has received further experimental support recently.<sup>2-4</sup>

The presence of grain boundaries in the wires requires a correction to the original expression used.<sup>5</sup> Thus:

$$\gamma = \sigma_{\epsilon=0} \cdot r [1 - (n/l)(ar)]^{-1} \quad [2]$$

where,  $n/l$  is the number of grain boundaries per unit length, and  $a$ , the ratio of grain boundary tension to free surface tension.

Alexander, Kuczynski, and Dawson<sup>3</sup> in studying the creep of gold wire in vacuum were unable to obtain reproducible values of the surface tension of gold. In plotting stress vs. strain for progressively longer times, they found that the stress at zero strain drifted with time from positive stress values to negative values. Similarly, for the surface tension of silver, reproducible values were obtained only when a purified helium atmosphere was substituted.<sup>2</sup> Evidently the evaporation rate of silver in vacuum is too high at the temperatures employed to obtain solid-gas equilibrium even in a similar metal enclosure. Thus reproducibility of results is lost.

## Experimental Procedure

The experimental procedure was much the same as that originally developed by Udin, Shaler, and Wulff with a few modifications and improvements. For greater accuracy in strain measurements, knots gave way to cut gage marks as shown in Fig. 1. These were made with a hand-driven lathe in which

razor blades served as cutting tools. Also a more precise cathetometer with a screw accurate to 0.00015 cm was used. The tests were conducted in an atmosphere of purified helium rather than in vacuum in order to avoid possible evaporation difficulties. Five mil wire of high purity gold (99.98 pct) was used.

After cutting in the gage marks, each wire of a series of about 12 was differently loaded by welding a gold ball to one end. This was done by dipping the end of the wire in a cooling gold droplet, previously melted on a charcoal block with a No. 2 acetylene torch. The other end of the wire was strung through a hole in a gold lid and twisted over the edge to hold the wires fixed and in suspension from the lid. The lid and mounted wires were then dipped in pure ethyl alcohol to dissolve any skin oils and dirt on the surface of the wires due to handling. Finally the lid was put in place on an alundum crucible lined with gold so that the wires hung freely within the gold-lined chamber. This whole assembly was next heated in a quartz nichrome wound tube furnace and heated for a few minutes at  $600^\circ\text{C}$  to soften the wires. After this anneal the wires were easily straightened with tweezers.

The wire assembly was finally annealed  $10^\circ$  to  $25^\circ\text{C}$  above the subsequent test temperature for 2 hr. This treatment allowed the grains to grow to equilibrium size and shape. After the anneal, the lid was mounted in front of the cathetometer. The gage length was measured by sighting the 40 power microscope on the upper lip of the lower gage mark for the first reading, then traveling up to the lower lip of the upper gage mark for the final reading. This procedure was repeated four times to give an average gage length value. In this manner the annealed gage length and the final gage length could be measured to determine the strains. During all measurements, grain counts were made.

F. H. BUTTNER, Junior Member AIME, H. UDIN and J. WULFF, Members AIME, are Instructor, Assistant Professor, and Professor of Metallurgy, respectively, Massachusetts Institute of Technology, Cambridge, Mass.

Discussion on this paper, TP 3187E, may be sent, 2 copies, to AIME by April 1, 1952. Manuscript, July 11, 1951. New York Meeting, February 1952.

Fig. 1—Loaded wire with cut gage marks.

The furnace used was an 18 in. quartz tube, 2 7/8 in. diam, wound with three nichrome tapered windings each controlled through a separate rheostat. The temperature was held to  $\pm 1^\circ\text{C}$  over the 4 in. hot zone by a Celestray temperature controller. Two thermocouples, one for the temperature controller and the other a traveling thermocouple, were used to check the temperature distribution over the length of the furnace. The helium used as furnace atmosphere was passed through an activated charcoal trap held in liquid nitrogen. A getter boat containing titanium powder was also kept in the hot zone of the furnace. This last precaution was shown by run No. 5 to be unnecessary.

Nine tests were made in purified helium, while

one test, No. 5, was carried out in air. The results of these tests are compiled in Table I, and shown graphically in Fig. 2. After a least square analysis of the data, the surface tension was calculated using eq 1. From these results the corrected surface tension was obtained with the aid of eq 2.

### Discussion and Conclusions

Test No. 5, run in air, gave a lower surface tension value than the tests run in helium. The result is however not sufficiently suppressed to indicate that oxygen adsorption is important as is the case in silver.<sup>4</sup> The short duration of run No. 9 at the lowest temperature exhibits so high a percentage of error that it was discarded.

The average value for the apparent surface tension was found to be  $1250 \pm 50$  dynes per cm over the range  $1280^\circ$  to  $1315^\circ\text{K}$ . For the corrected value, eq 2 was used, where  $n/l = 75$ , and  $a = 0.300$ , which together give a correction factor of 0.889. The average corrected value over the same range of temperatures then becomes  $1400 \pm 65$  dynes per cm. The value for  $n/l$  was computed from the average grain count with respect to the average annealed gage length of ten randomly chosen wires. The value for the constant,  $a$ , was computed from the average grain boundary angle for 250 readings by the reflected light method of Greenough and King<sup>6</sup> where the grain boundary angle averaged  $163^\circ$ .

The least square line drawn through the points of Fig. 2 has a slope of  $-0.433$ , which is in fair agreement with the Eötvös slope of  $-0.354$ . For silver<sup>2</sup> much closer agreement obtains.

### Structure of the Gold Wires

The wires were of the typical bamboo or reed-like structures observed before.<sup>1-3,7</sup> An excellent series of micrographs of gold wires appear in a paper by Alexander, Dawson, and Kling,<sup>7</sup> showing kinking, offsetting, and what appears to be bulging. Similar effects were observed in the experiments reported here.

The phenomena of kinking and offsetting is critically discussed by Herring,<sup>8</sup> who predicts this behavior on the basis of his theoretical treatment. Kinking appears to be the result of rotation of the grains about an axis lying in the grain boundaries. Offsetting, which is seen only in heavily loaded wires, results from the normal viscous behavior of grain boundaries.

Concerning the matter of bulging, Zener<sup>9</sup> has shown theoretically that the surface tension forces in wires of this type should cause each wire to break up into a series of small connected spheres. Alexander, Dawson, and Kling conclusively demonstrated the reality of Zener's prediction by heating for 120 hr a gold wire lying in an alundum boat at  $1055^\circ\text{C}$ . It is thought that if this tendency is appreciable under the conditions of the experiments, accordingly appreciable error might be expected in the final results. As a matter of fact, Alexander, Dawson, and Kling attribute some erratic behavior in lightly loaded wires in their experiments to this phenomenon.

In the experiments reported here as well as those reported by Funk, Udin, and Wulff, dummy wires were attached to and never removed from the same lid used throughout all the tests. Some of the dummy wires were plastically strained so as to introduce artificial bulges at the restrained region of the grain boundaries, and waists at the regions of no restraint in the middle of grains. These dummy

Fig. 2—Average surface tension vs. temperature  $^\circ\text{K}$  showing Eotvos line.

wires accumulated at least 200 hr under the exact test conditions of these experiments. In no case was a visible incipient breakup in the unstrained wires observed nor was an aggravation of the bulged condition of the strained wires seen. Cut gage marks also introduce a start toward the expected breakup of the wires. But actually here the opposite effect is observed in that the gage marks over a period of time at the test temperatures tend to disappear by smoothing over.

Apparent bulges appear in mounted and polished specimens. A plane section as formed by polishing through a kink produces what appears to be a sizeable bulge as shown in the line drawing of Fig. 3. Also bulges may appear on polished specimens due to strains introduced by mounting the specimens in bakelite.

Even if bulges were to exist, they may not exert as strong an influence as might at first be thought. If it is assumed for the moment that the wires do change into what might be called an idealized string of small spheres, or series of waists and bulges, and if it is also assumed that the idealized condition evolves by removing a ring of material from the cylinder to form a waist, and then putting it back on the cylinder slightly above the waist to form a bulge—by doing this all along the wire a contoured bulge and waist condition is created. In this process, no elongation or contraction is effected. Comparing the strain of a contoured wire to a cylindrical wire after a period of time at the test temperature, excessive elongation at the waists will be offset by deficient elongation at the bulges. Thus, the overall elongation of the contoured shape should be the same as a uniform elongating cylinder. The sum of the vertical components of surface tension over the contoured surface equals the vertical tension of the original cylindrical surface. Thus, in this idealized condition, no difference in important behavior can be found from that of a cylindrical wire.

Although there is no reason to believe that the wires will assume the idealized condition, nevertheless any bulge and waist model would necessarily be some approach to the ideal. Only the departure of the actual from the ideal would introduce error into the results of the experiments.

The tendency of the wires to spheroidize is observed to be vanishingly small for the configuration of experiment described here. Visible beginnings of spheroidization would in themselves introduce only second-order errors, insofar as they depart from the above idealized picture. Thus, any errors due to a

Fig. 3—Construction of the polished surface cutting through a kink.

tendency to bulge are lost in the normal experimental uncertainties of the technique.

Summary

Using a modified Udin, Shaler, and Wulff technique the surface tension of gold in purified helium was found to be  $1250 \pm 50$  dynes per cm. Using the Udin correction for grain boundary energy, this becomes  $1400 \pm 65$  dynes per cm for temperature range  $1280^\circ$  to  $1315^\circ\text{K}$ .

It has been observed that no spherical breakup of the wires is present in these experiments. Bulges appear on polished specimens, but this appears to be a spurious effect of the mounting and polishing technique. Ideas are presented indicating that the experiments could be carried out to the beginnings of visible spheroidization without introducing a significant error in either the value of surface tension or the rate of axial creep.

## Eutectoid Decomposition of the Delta Phase of the Copper-Tin System

by C. C. Wang and M. Hansen

THE  $\delta$  phase of the Cu-Sn system ( $\text{Cu}_{31}\text{Sn}_8 = 32.53$  pct Sn) was considered to be stable down to room temperature until Owen and Iball<sup>1</sup> showed by X-ray analysis that it undergoes a eutectoid decomposition into the  $\alpha$  and  $\epsilon$  phases at a temperature near 300°C. Their findings have been confirmed by other investigators,<sup>2-5</sup> all of whom used X-ray diffraction studies of powdered specimens. The transformation temperature has been reported by various authors as lying between 300° and 380°C. To our knowledge, no microscopic evidence of the eutectoid reaction has been published, as yet.

It was in connection with other work that long-time annealings at 300°C were conducted with alloys containing 22, 32.6, and 35 pct Sn (nominal compositions) prepared from electrolytic copper and electrolytic tin and cast in a small iron mold. The specimens were first annealed at 700°C for 5½ hr and quenched from 400°C after cooling to, and annealing at, that temperature for 9½ hr. After this

annealed 32.6 pct alloy, which was intended to consist entirely of  $\delta$  phase. Due to some loss in copper on melting, the composition is slightly higher in tin. Accordingly, the sample after quenching from 400°C consisted of grains of the  $\delta$  phase with the  $\epsilon$  phase arranged along the grain boundaries and as a Widmanstätten precipitate within the  $\delta$  grains. After an annealing time of 63 days, the eutectoid decomposition,  $\delta \rightarrow \alpha + \epsilon$ , is still in its early, initial state. The pearlitic type of eutectoid is nucleated at the  $\epsilon$  crystals, preferably those surrounding the grain boundaries of the  $\delta$  phase. The appearance of the  $(\alpha + \epsilon)$ -eutectoid in the 35 pct Sn alloy was very similar to that shown in Figs. 2 and 3. Again, the eutectoid decomposition nucleated at the  $\epsilon$  phase and proceeded from there into the  $\delta$  areas.

As is evident from Fig. 2, the rate of decomposition of the  $\delta$  phase at 300°C is extremely sluggish: In the representative area shown only about 5 pct of the  $\delta$  phase has undergone the eutectoid trans-

Fig. 1—About 22 pct Sn. X750.

Fig. 2—About 33 pct Sn. X100.

Fig. 3—About 33 pct Sn. X500.

Figs. 1 to 3—Microstructure of Cu-Sn alloys after annealing for 63 days at 300°C. Etchant,  $\text{FeCl}_3$ .

treatment the sample with 22 pct Sn was cold worked for 15 pct reduction in thickness; the 32.6 and 35 pct alloys were too brittle to be cold worked. The final anneal at 300°C was done in a sealed pyrex glass bulb for 63 days.

Fig. 1 represents the microstructure of the annealed alloy with 22 pct Sn. It shows primary  $\alpha$  solid-solution crystals in a matrix of the  $(\alpha + \delta)$ -eutectoid formed at 520°C. The  $\alpha$  crystals contain  $\delta$  inclusions which precipitated from  $\alpha$  due to the decrease in the solubility of tin in copper with fall in temperature. The decomposition of the  $\delta$  phase into  $\alpha$  (light) and  $\epsilon$  (dark) can clearly be seen in some areas of the  $(\alpha + \delta)$ -eutectoid matrix. However, the decomposition is far from being completed, even after the long-time anneal used.

Figs. 2 and 3 depict the microstructures of the

formation after annealing for 63 days. On the other hand, Owen and Williams<sup>2</sup> have reported that X-ray photographs of powdered samples with between 17.5 and 34 pct Sn did not show  $\delta$  lines after annealing for only five to seven days at 300°C. This is in accordance with the fact that the rate of reaction in powdered samples is higher than in massive specimens, as a result of the excess free energy of the powder (due to its greater surface area).

The authors wish to express their thanks to C. A. Johnson for preparation of the micrographs.
